Digital Twin Generation from Visual Data: A Survey

Andrew Melnik, Benjamin Alt, Giang Nguyen, Artur Wilkowski, Maciej Stefańczyk, Qirui Wu, Sinan Harms, Helge Rhodin, Manolis Savva, and Michael Beetz

Abstract—This survey explores recent developments in generating digital twins from videos. Such digital twins can be used for robotics application, media content creation, or design and construction works. We analyze various approaches, including 3D Gaussian Splatting, generative in-painting, semantic segmentation, and foundation models highlighting their advantages and limitations. Additionally, we discuss challenges such as occlusions, lighting variations, and scalability, as well as potential future research directions. This survey aims to provide a comprehensive overview of state-of-the-art methodologies and their implications for real-world applications. I. INTRODUCTION

 \mathbf{D} IGITAL Twins (DT)¹ are virtual representations of products, processes, and facilities that enterprises use to design, simulate, and operate their physical counterparts.

In the scope of this survey, we define Digital Twins as 3D models enriched with processes and semantic connections, similar to those in computer game environments and industrial CAD models. These models can range in accuracy from approximated 3D representations, like *Digital Cousins* [1] to highly detailed virtual replicas of real-world environments known as *Digital Twins*. Our focus will be on methodologies and understanding required to improve the accuracy of

Recent advances in automatization of Digital Twin reconstruction from visual data provide opportunities for various domains, including robotics [2, 3], architecture, facility management, industrial fabrication, gaming, video stream compression, and virtual reality.

Traditionally, the creation of Digital Twins has relied on specialized hardware such as LiDAR scanners or hand-crafted CAD models. Recent advances in computer vision and machine learning, such as 3D Gaussian Splatting (3DGS), NeRF, and diffusion models, have opened new possibilities for simplifying this process using widely accessible video data. Videos, captured with ubiquitous devices such as smartphones, offer a rich source of spatial and visual information that can be leveraged for Digital Twins generation.

Another source of visual data is short videos generated by Video Diffusion Models (VDM) [4], which often suffer from a lack of physical plausibility. These limitations of VDMs can be mitigated by generating and animating Digital Twins based on the synthesized video content. Moving forward, the next frontier in 3D representation lies in enriching these DT models by integrating both the physical [5] and semantic [6] properties of objects.

Moreover, by analyzing demonstrations, such as a person interacting with a chest of drawers or a light switch, models can begin to absorb deeper contextual properties beyond mere geometry, like articulation of parts, hierarchical structure and connectivity, interaction properties, rules, associated processes, material properties, audio patterns, etc.

This survey focuses on the generation of Digital Twins (Figure 1) from images and videos, exploring the methods, challenges, and innovations that enable this transformative process. We aim to address key questions, including how to accurately reconstruct indoor environments, integrate semantic information, and ensure scalability across diverse use cases. The goal is to present approaches that not only enhance the fidelity of digital twins but also reduce the barriers to their adoption. We also highlight practical applications and outline future directions to advance the field further.

II. SHAPE RECONSTRUCTION

A. Mesh, CAD, 3DGS

Digital shape representations are usually based on mesh models, CAD models, and 3D Gaussian Splatting (3DGS) - each having distinct advantages. **Mesh** representation is

 COMPARISON OF 3DGS, MESH, AND CAD MODELS

using interconnected polygons (triangles or quads), making it efficient for real-time rendering, gaming, and 3D printing, though it lacks precise parametric control. CAD representation employs mathematical curves (NURBS, B-Rep) to create highly accurate, editable, and feature-based models, making it ideal for engineering, manufacturing, and design applications. 3D Gaussian Splatting represents objects using point-based Gaussian functions with attributes like color, opacity, and density. This method excels in photorealistic, view-dependent rendering and is particularly useful for neural scene representations and volumetric graphics. Althoughugh mesh and CAD models are more structured and interpretable, 3DGS offers a continuous and memory-efficient alternative for immersive applications (see Table I). The growing number of new methods for automated 3DGS reconstruction is establishing 3DGS as one of the key representations for approximating 3D scenes from visual input.

B. Video to intermediate 3D representations

a) COLMAP & Point Clouds: COLMAP [7] is a generalpurpose Structure-from-Motion (SfM) pipeline. SfM [8], is a computer vision technique used to reconstruct a 3D representation of a scene from a set of 2D images taken from different viewpoints (Figure 2 b). The process involves detecting and matching features across images, reconstructing the motion of the camera, and using triangulation to recover the 3D structure of a scene [7]. The key part of SfM is determining both 3D geometry of the scene and the camera's position and orientation relative to that geometry. SfM typically begins with feature detection, where key points such as edges, corners, and texture detected in each images using matching algorithms, ranging from classical techniques such as SIFT [9] to more recent deep learning-based approaches like SuperGlue [10], R2D2 [11], and LoFTR [12], which utilize neural networks or transformer architectures to achieve SOTA performance.

The corresponding features are then matched between the images, and by analyzing how key points move between the images, the algorithm determines the camera positions and orientations and camera intrinsic parameters. This allows for the reconstruction of 3D points using triangulation. To refine

the points and camera parameters, SfM uses bundle adjustments [13], reducing projection errors for higher accuracy. The result of this process is a sparse 3D point cloud. A point cloud is a collection of discrete points in 3D space that represents the surface geometry of an object or a scene. Each point has (X, Y, Z) coordinates, defining its position in space. Additional attributes such as color, intensity, and normal vectors can be stored with each point to enhance visualization and processing. These point clouds serve as the foundational data structure for many 3D modeling techniques, including mesh generation and virtual scene reconstruction. In some cases SfM is extended with Multi-View Stereo (MVS) to generate a dense point cloud that captures more details of the scene [14].

b) SLAM: Simultaneous Localization and Mapping is a fundamental concept in robotics and computer vision: estimating a camera's motion in an unknown environment while building a 3D map of the surroundings. Previously SLAM systems used point clouds [20], surfels [21], or volumetric representations [22, 23, 24], relying on handcrafted feature tracking and pose estimation pipelines. While effective for basic localization, these systems struggle with photorealism, robustness in dynamic or low-texture environments. Recent advances introduce differentiable, learning-based representations, most notably 3D Gaussian Splatting [15], to address these limitations. Originally designed for novel view synthesis with known camera parameters, recent works [25, 26, 27] adapt 3DGS for SLAM by jointly optimizing camera poses and scene geometry via online tracking and incremental mapping. The differentiability of 3DGS enables gradient-based tracking using geometric (depth accuracy) and photometric (color consistency) loss functions over rendered and observed frames [25, 26, 27, 28, 29, 30, 31]. SLAM systems can also benefit from the compactness and continuity of Gaussian primitives improving the memory efficiency. Several works address this topic by compressing Gaussian attributes [32], reducing the number of Gaussian primitives by introducing opaque/transparent Gaussians [33], or introducing uncertaintyaware Gaussian fields to balance tracking robustness [34].

In terms of pose estimation, most systems assume a constant velocity or speed assumption [25, 26, 28]. Initial poses are then

Fig. 2. Visualization of key principles in 3D Gaussian Splatting pipeline (a). Gaussians are initialized from a sparse point cloud (b), for fast rendering the image is split into tiles using differentiable rasterization (c). Projected Gaussians inside a tile's view frustum are sorted by depth (d), this allows α -blending to determine the final color of each Gaussian (e). During optimization, adaptive densification controls the number of Gaussians to minimize reconstruction errors (f). View-dependency of color can lead to inconsistency when rendering from different views, flattening the z-scale can improve consistency (g). Figure compiled from (a)-[15];(b)-[16]; (c),(e)-[17];(d)-[18];(f)-[15];(g)-[19]

refined through differentiable rasterization-based optimization, point-to-plane ICP alignment [35] or (semantic) bundle adjustments [29, 31, 32, 36]. Coarse-to-fine tracking strategies, optimizing estimates in multiple scales, further boost accuracy and minimize initialization errors [27, 33, 37]. To prevent drift and error accumulation, some systems use keyframe selection with global or hierarchical bundle adjustment framework, ensuring that the estimated camera trajectories remain stable over time [31, 35]. Other methods, incorporate Iterative Closest Point (ICP) techniques and graph-based optimization, leveraging both front-end and back-end processing for large-scale scene reconstruction [33]. While most systems use monocular RGB-D input and adopt optimization techniques, other methods propose the integration of multi-senor data, such as IMU, LiDAR, or stereo data for improved accuracy and camera pose propagation [31, 38].

Despite these commonalities, differences emerge in the mapping strategies. They vary from coarse-to-fine refinement using sparse pixel initialization and depth-based updates, to silhouette-guided rendering that incrementally refines poses, to dividing the scene into sub-maps for localized optimization [25, 26, 27].

Going beyond static mapping, newer semantic SLAM systems

imbue semantic features directly into Gaussian parameters. This enables joint optimization of semantics, geometry, and appearance in a unified framework [29, 37, 39]. In parallel, dynamic SLAM systems adapt 3DGS to model non-rigid environment such as deformable tissues in endoscopy. These systems integrate temporal deformation fields, occlusion-aware loss function, and surface-aligned regularization to capture motion while maintaining consistent tracking [30, 40, 41]. SLAM in unconstrained environments often deals with sparse observations, occlusion, or ambiguous input. Recent work proposes rendering-guided densification to refine geometry by injecting new Gaussians in underrepresented areas [28]. Other methods reduce the number of splats by modeling scenes with hybrid Gaussians that selectively capture solid vs. transparent structures [33].

c) 3D Gaussian Splatting points: 3D Gaussian Splatting Radiance Field [15], more widely known as 3D Gaussian Splatting (3DGS), is an explicit radiance field-based scene representation that uses 3D Gaussian primitives instead of traditional point clouds. Each 3D point in this representation is not just a simple coordinate, but a learnable 3D Gaussian distribution. More concretely, a Gaussian is characterized by a covariance Σ and a center (mean) point μ ,

$$G(x) = e^{-\frac{1}{2}(x-\mu)^{\top} \Sigma^{-1}(x-\mu)}$$
(1)

The means of 3D Gaussians are initialized by a set of sparse point clouds (e.g. obtained from SfM). Each Gaussian is parameterized by its center position $\mu \in \mathbb{R}^3$, spherical harmonics (SH) coefficient $c \in \mathbb{R}^k$ (k representing degrees of freedom) for view-dependent color, rotation factor $r \in \mathbb{R}^4$ (in quaternion rotation), scale factor $s \in \mathbb{R}^3$ and opacity $\alpha \in \mathbb{R}$. The covariance matrix Σ describes an elipsoid configured by a scaling matrix $S = \text{diag}([s_x, s_y, s_z])$ and rotation matrix $R = q2R([r_w, r_x, r_y, r_z])$ where q2R() is a function to construct a rotation matrix from a quaternion. The covariance matrix can then be computed as,

$$\Sigma = RSS^{\top}R^{\top} \tag{2}$$

To optimize the 3D Gaussian parameters to represent a scene more accurately, they need to be rendered into images in a differentiable manner. Therefore the 3D Gaussian points are projected onto a 2D image plane in a process called splatting [42]. This is done by applying a viewing transformation Wand the Jacobian of the affine approximation of the projective transformation J to the covariance matrix Σ to get a projected 2D covariance matrix $\Sigma' = JW\Sigma W^{\top}J^{\top}$ in camera coordinates. To achieve fast rendering and allow approximate α -blending, the final image is split into 16×16 tiles (Figure 2 c). Then, for each tile, the projected Gaussian that intersect with the tile's view frustum are sorted by depth (Figure 2 d). Consequently, at a given pixel the color C is computed by α compositing the opacity α and color c, computed from spherical harmonics parameters, of overlapping 3D Gaussians (Figure 2 e)

$$C = \sum_{i \in \mathcal{N}} \mathbf{c}_i \alpha_i \prod_{j=1}^{i-1} (1 - \alpha_j)$$
(3)

During optimization, parameters are initialized from SfM point clouds or random values. It employs Stochastic Gradient Descent (SGD) [43] with an L1 and D-SSIM [44] loss function, optimizing against ground truth and rendered views. To address under- and over-reconstruction, periodic adaptive densification is applied, adjusting points with high gradient variations and eliminating those with low opacity (Figure 2 f). This enhances scene representation quality while minimizing rendering errors.

d) Surfels: Surfels, or surface elements, are point-based rendering primitives used to approximate surfaces through oriented point samples enriched with attributes such as position, normal vector, color or texture [45]. Originally presented as an alternative to mesh-based representations with no explicit connectivity and therefore ease of manipulation, this idea resurfaced in recent attempts to address some of the shortcomings of 3D Gaussian Splatting. Despite their efficiency and photorealistic rendering, 3DGS shows limitations with surface reconstructions. 3D Gaussian splats are of volumetric, view-inconsistent nature, therefore limited in accurate geometric representations. To address this, recent methods share a unifying principle of transforming unstructured volumetric splats

into compact, surface-aware, and view-consistent primitives - such as disks, planes, or flattened ellipsoids (Figure 2 g). These methods introduce 2D-oriented Gaussians that lie explicitly on the scene's surfaces [19, 46] enforced by geometric regularization, e.g. depth-normal consistency or multi-view alignment. A parallel strategy, taking direct inspiration from surfels, collapses the z-scale of 3D Gaussians to create Gaussian surfels, enabling explicit normal encoding and enhanced optimization stability [47]. Beyond geometric fidelity, other approaches emphasize compactness and rendering efficiency. By applying 2D Gaussians ultra-fast image representation and compression can be achieved avoiding volumetric overhead while preserving detail [48]. Other approaches, meanwhile, extend 2D Gaussian Splatting by attaching per-primitive textures, improving on high-frequency appearance modeling and disentangling geometry from texture [49, 50].

C. Impact of input sources

a) Monocular video-based Reconstruction: Reconstructing 3D scenes from 2D videos usually requires multi-view videos to be captured. Although they only see the scene from one view point at a time, depending on the method on how the video is captured, it can still contain cues that are effectively similar to multi-view capture [51].

Traditional 3D reconstruction approaches often perform well under controlled conditions but face challenges inthe-wild, where input data—such as casual monocular videos—exhibit wide variations in lighting, exposure, and camera settings. One strategy to handle such appearance variability is to condition the scene representation on learned appearance embeddings, allowing the color of each 3D point (or Gaussian) to adapt based on the input image. This can be further enhanced by incorporating image-dependent opacity to suppress transient or inconsistent elements across views [52]. Another direction addresses the issue of incomplete or uneven view coverage, common in casually captured videos. Here, generative priors, such as diffusion-based, can guide the synthesis of unseen viewpoints, effectively filling in missing information and improving reconstruction quality [53].

Another problem that arises with in-the-wild captures, is different kinds of blur, such as motion, defocus, and downsampling blur. These degradations can significantly affect the accuracy of SfM and lead to poor reconstruction results, especially when initial camera pose estimate are unreliable. A common strategy across recent works is to explicitly model the blur to achieve better alignment between rendered and observed frames. One approach simulates the blur by rendering multiple sub-frame viewpoints and averaging them to explain the observed blur [54]. Another incorporates the blur estimation process directly into training by synthesizing blurred from interpolated sharp images, rendered along an estimated camera trajectory [55]. Alternatively, image-space modeling has been proposed, where blur is captured through spatially-varying per-pixel kernels predicted by a dedicated Blur Proposal Network. To improve stability when initializing from sparse point clouds, this approach uses a coarse-to-fine training schedule to refine both kernels and reconstructions

incrementally [56]. Mobile devices often rely on rolling shutter cameras, which capture image rows sequentially. When the camera moves rapidly, it introduces temporal distortions that create warping artifacts, violating the assumption of static global camera poses - a premise in many 3D reconstruction techniques. To address this, a recent work proposes a model that treats camera pose as time-varying during exposure, enabling simulation of these effects [57]. This is achieved by leveraging visual-inertial odometry (VIO) to estimate perframe velocities, which inform a differential rendering pipeline capable of explaining rolling-shutter and motion blur effects.

b) Handling non-calibrated cameras: In the context of 3D reconstruction, non-calibrated cameras refer to cameras for which the intrinsic and extrinsic parameters are either unknown or not predetermined. These parameters are crucial for accurately mapping 2D images into 3D space and are usually pre-computed from COLMAP [7]. The SfM (Structure-from-Motion) algorithm depends on dense image input, the amount of overlap, and the number of feature correspondence across those images to correctly estimate camera parameters. This process can be, depending on the input, time consuming or fail due to sensitivity to feature extraction errors, difficulties in handling textureless and repetitive regions [58], and sparse input data. To weaken the dependence on SfM algorithms, research presents two main paradigms: pose refinement and pose free reconstruction. Pose refinement methods focus on improving initial, often imprecise pose estimates by optimizing the camera parameters through iterative refinement using 3D scene reconstructions such as 3DGS. These methods work under the condition that initial pose estimates are available, precomputed either through COLMAP or other means. The poses are then refined typically by render-and-compare strategies or 2D-3D feature matching [59, 60]. These methods provide fast and reliable improvements, when initial poses are available but ill poised, however in cases of completely unknown parameters they fail. For this reason, pose free methods try to loosen the dependency on COLMAP, by jointly estimating 3D geometry and camera parameters directly from unposed images. This is achieved through efficient methods like pixel-aligned point maps, depth refinement and matching-aware pose networks [58, 61, 62, 63]. Some methods integrate pretrained vision transformers to initialize point maps and Gaussian primitives and enable scalable training across unordered and large-scale image sets [64, 65]. These strategies enable fully differentiable pipelines that jointly optimize both intrinsic and extrinsic camera parameters along with scene geometry, achieving state-ofthe-art rendering and pose accuracy without any precomputed camera input [66].

c) Wide-angle (fisheye) lenses: Most 3DGS frameworks struggled with lens distortion artifacts when processing wideangle imagery with a large field of view (FOV), leading to noisy and hazy 3DGS reconstructions. A recent self-calibrating framework [67] has introduced a resampling strategy that solves this problem by combining invertible residual networks [68] with explicit grids.

d) Integrating LiDAR and RGB-D data: RGB-D or color-depth cameras are made up of two main components: a standard camera capturing RGB data and a projector-sensor system capturing depth data. This system can be used in different ways, but the one of interest is to measure distance and shape of any object by projecting structured light on to a scene. This data combined with the color information from the RGB camera can then be used to construct a colored point cloud [69]. Depth data can here improve robustness in ambiguous or textureless scene by providing geometric cues where RGB fails [25, 34]. In many systems depth data is utilized through depth-aware loss terms or direct ICP alignment [27, 31, 35]. Additionally it can be utilized for more precise surface modeling and 3D point placement or constrain 3D structures across different views [28, 29, 33, 39]. A major drawback, however, is the short effective range of depth sensors. LiDAR sensors on the other hand use one or more laser sensors to measure a scene by bouncing laser beam off of objects. The technology is quite mature and often used in the automotive or industrial sectors for distance measures [69]. In a smaller form factor, the technology is also available on certain Apple hand held devices². Without the range limitation of depth cameras, LiDAR can provide precise, and high-range depth data, which can be useful in outdoor or very poorly textured and dark environments [38]. LiDAR points together with RGB data for color can directly be used to initialize 3D point-based representations, like Gaussians, for environments where visual features are sparse or unreliable [38].

e) Domain-free 3D scenes: Recent advances in 3D generative modeling have emerged aroung 3D Gaussian Splatting (3DGS) as a representation compatible with diffusion-based pipelines. Central to nearly all methods is the integration of 2D diffusion priors, particularly Stable Diffusion variants. Nearly all recent works - spanning from object-level generation [70, 71, 72, 73, 74, 75, 76, 77, 78], scene-level synthesis [36, 79, 80, 81, 82], and 4D content modeling [53, 83, 84, 85, 86, 87, 88] - adopt Score Distilation Sampling (SDS) [89] or closely related guidance techniques to supervise the generation of semantically aligned, view-consistent 3D content from sparse input such as text, RGB, or RGB-D images. A common architectural pattern involves multi-stage generation, where coarse geometry, typically initialized from text [90, 91, 92] or images [72, 93], is refined through optimization [75, 79] or amortized inference [71, 73, 93, 94, 95]. Additionally recent structured representations [90] allow 3D convolution and parameter-efficient training.

A key challenges lies in ensuring multi-view consistency. To enforce spatial coherence across novel views, approaches like patch-level hypergraph reasoning [76], epipolar attention [72], volumetric pruning [73], geometric diffusion [75], and Gaussian alignment losses [87] have emerged, while at the same time, a growing focus on efficiency has led to the reduction of inference time by significant amounts through training free-methods [94], feedforward networks [74, 93], or reduced sampling steps [77, 85].

Beyond object-centric synthesis, several frameworks introduce solutions for scene-level generation with controllability. To this end, many frameworks incorporate layout-aware priors,

²https://www.apple.com/newsroom/2020/03/apple-unveils-new-ipad-prowith-lidar-scanner-and-trackpad-support-in-ipados/

derived from large language models (LLM), to structure object placement, enhance composition, and support interactive editing through semantic inpainting [96] and multi-entity optimization [36, 80, 81, 92]. Panoramic image lifting has further enabled globally coherent 360° 3D scenes [82].

Parallel to static scene generation, 4D generative modeling extends 3DGS, representing dynamic content via deformable Gaussians optimized with spatio-temporal regularization [83, 84, 86, 87]. While some approaches use LLM-guided compositional motion [92], others enforce motion realism from monocular input using neural bone representation [53] or adaptive densification [88]. Notably, to allow modular control and motion transfer, compositional 3D models segment scenes into deformable entities [92], while real-time pipelines [85] focus on acceleration over complexity. Overall, controllability varies from implicit optimization in static generation [70, 73] to explicitly guided scene editing and motion planning [36, 92, 97].

D. Sparse view and reconstruction from a single image

a) Reconstruction from Images: Reconstructing 3D scenes from images can be challenging especially when there is a lack of dense multi-view input (see Figure 3). Constructing high-quality 3D Gaussian Splatting (3DGS) scenes directly from image inputs has become an active research direction, expanding 3DGS from multi-view reconstruction into minimalview or few image scenarios. Technically these methods can be categorized in to three main approaches: optimization-based reconstruction, amortized feed-forward prediction, and hybrid refinement with generative priors. Optimization-based methods [116, 117] iteratively reconstruct 3D Gaussians with the use of structural prior guidance, such as monocular depth, multi-view flow, or visual hulls. Through these regularized loss terms they can enforce view-consistent geometry and can be optimized through differentiable rendering. In contrast, amortized models [93, 118, 119, 120] focus on training neural networks to directly infer 3D Gaussian parameters from images using convolutional or transformer-based architectures. These models usually incorporate camera pose or ray-based conditioning, and adopt innovative network architectures - for example scan-ordered sequential networks or hybrid token designs to efficiently scale the prediction to large numbers of Gaussians while preserving fidelity. A third emerging paradigm combines explicit Gaussians with 2D diffusion-based guidance for appearance refinement, occlusion completion, and even editing [121, 122]. These methods begin with a coarse 3D reconstruction and then render multi-view image, which are edited or enhanced using diffusion models. These enhanced views are then used to re-optimize the 3D scene to achieve higher fidelity even with as sparse input as a single image [121, 122, 123]

Although neural 3D reconstruction has made significant progress [125, 126], they usually depend on densely captured multi-view data with well-initialized poses for each frame, e.g, pre-processed with COLMAP [7].

Next generation frameworks, like InstantSpat [127] or Dust to Tower [63] reconstruct 3D scenes from sparse-view images

Fig. 3. Generation of mesh models. Image from [124]

without relying on Structure-from-Motion (SfM). However, these methods still use models like DUSt3R [128] or MASt3R [129] to predict pixel-aligned dense stereo correspondences between sparse images and initialize camera parameters. They build a co-visibility graph to align stereo point maps across multiple views. Then it jointly optimizes 3D Gaussian Splatting representation and camera poses using gradient-based photometric error minimization. Additionally they use Monodepth models, like Depth Anything V2 [130] for depth estimation from a single image.

Ultimately, fully interactive Digital Cousin [1] scenes can be generated from a single RGB image. Digital Cousins [1] are scenes that, unlike Digital Twins, do not exactly replicate real-world counterparts but retain key geometric and semantic affordances. Open vocabulary objects [131, 132] in the RGB image are identified using GPT-4. GroundedSAMv2 makes a segmentation of the identified objects. Depth information is estimated using Depth Anything V2 [130]. Extracted 3D objects are matched to digital assets from a dataset (e.g., BEHAVIOR-1K [133]) with CLIP similarity scores and DINOv2 embeddings to find the best-matching digital assets. The closest matches are selected, assigned appropriate orientations, and placed in a physically plausible scene. Objects are adjusted to remove physical penetrations and ensure stability. CAST [108] offers several improvements over the concept of Digital Cousins [1]. CAST's primary goal is to recover high-quality 3D scenes with detailed geometry, vivid textures, and physically sound interdependencies with physics-aware correction step. CAST [108] is a generationdriven scene reconstruction approach where 3D meshes for individual objects are generated and then aligned, while Digital Cousins rely on retrieving existing 3D assets from a dataset. SINGAPO [134] has a similar pipeline as Digital Cousins [1], however, SINGAPO [134] is focused on generation of articulated parts of household object from a single image, like refrigerators, cabinets, or microwaves.

Another line of works tackle both tasks of 3D object

TABLE II SUMMARY OF OBJECT-LEVEL SINGLE-VIEW 3D SCENE RECONSTRUCTION AND MODELING METHODS.

retrieval and object alignment to the image in a pipeline of creating synthetic 3D scene [109, 110, 111, 112, 135], where objects are detected, segmented [136], aligned, and CAD models are retrieved and posed to form a 3D scene. These works typically require large-scale data of image-CAD pair annotations to train the model in an end-to-end manner, which makes them hard to generalize due to tremendous efforts needed to collect expensive data. Recently, several zero-shot methods [1, 115] have been proposed to mitigate the problem of scene data scarcity by leveraging visual foundation models and Large Language Models (LLM). Digital Cusion [1] simply ranks 3D object candidates using DinoV2 [137] features on multi-view renderings and ask GPT40 to pick the top-K best matching ones. Diorama [115] proposes a hierarchical retrieval strategy where both text and visual modalities are employed for better retrieval results using DuoDuoCLIP [138].

E. Retrieving Object Mesh Models

Typical 3D shape retrieval measurements require both the ground-truth shape and retrieved 3D shapes to compute either retrieval accuracy or point-based reconstruction scores, such as Chamfer Distance (CD), Normal Consistency (NC) and F-score F1^t conditioned on point-wise distance t that indicates the strictness of points being accurately reconstructed. These metrics can be directly used as shape similarity to retrieve 3D shapes given an object point cloud as query. We note that point-based metrics are sensitive to the point sampling method and the number of sampled points. The work [139] shows that Under the same sampling condition, NC and F1^t tend to

rank unrelated shapes higher compared to CD, which either present distinguishable geometric structure or have wrong categories. Overall, CD is a more robust point cloud-based similarity score for shape retrieval that outputs reasonable shape ranking without the need to tweak hyperparameters. Besides 3D representation with explicit geometry such as point clouds and voxel, 3D shapes can also be represented as multiview images. A prescribed approach [140] represent a 3D shape as light-field descriptor (LFD), computed from a set of pre-rendered binary masks, and retrieve the target shape by comparing L1 distance of features.

More recently, learning-based methods are developed to advance the progress in different variants of the 3D shape retrieval task, involving querying of shapes from single-view images [110, 111, 141, 142], text [143, 144], voxels [112], point clouds [145] and other 3D objects [146]. To align the different modalities of the same physical entity, queries and 3D objects are usually encoded into a joint-embedding space that learnt in an end-to-end manner using triplet or contrastive losses. In such case, retrieval can be achieved by fetching the 3D object with the minimal distance in the high-dimensional embedding space to the query object. The distance is usually messured by L2 norm or cosine distance. Given an image query of the target object, CMIC [141] achieves state-of-the-art performance on retrieval accuracy by using instance-level and category-level contrastive losses. To handle different texture and lighting conditions in images, [147] proposed to synthesize textures on 3D shapes to generate hard negatives for additional training. [148] used a deformation-aware embedding space

Fig. 4. Summary on 3D shape retreival paradigm.

so that retrieved models better match the target after an appropriate deformation.

The natural limitation of learning a image-CAD jointembedding space is that it would consume large-scale imageshape pair annotations to achieve generalizability to novel object instances and categories, which is empirically infeasible and expensive. One promising solution is to investigate the use of vision-language model (CLIP [149]) to guide the alignment of 3D shape embeddings. ULIP [150] is one of the pioneers that align text, image and 3D modalities. It uses frozen CLIP text-image encoders, and trained only the point-cloud encoder. However, the generalizability of these works were limited by the available dataset size at the time. OpenShape [151] and ULIP-2 [152] are among the first to scale up paired text-image-3D training data to train a point cloud encoder aligned with the CLIP embedding space multi-modality contrastive learning. They take advantage of combined largescale 3D shape datasets [153, 154] to recover real-world data distribution beyond a fixed number of classes and pretrained LVLMs (GPT-4v) for rendering captioning to generate paired text description. Uni3D [155] maps point cloud patches to image patches within pre-trained ViTs to align the 3D point cloud features with the image-text aligned features. In contrast to aforementioned existing works, DuoDuoCLIP [138] learns shape embeddings from multi-view images instead of point clouds that show better generalization performance and more light-weight hardware requirements.

III. LIGHT AND REFLECTIONS

A. Relighting

Fig. 5. Example rendering pipeline for Gaussian splatting with reflections [156]

One of the crucial aspects of the digital twin environments is the ability to impact the scene lighting (to simulate different conditions like time of day). While the spherical harmonics used in the Gaussian Splatting allow for some view-dependent color modeling, information about the whole scene lighting is baked into them and the basic rendering pipeline doesn't allow for any light modifications. This problem was identified quickly after the 3DGS publication, with authors expanding the rendering pipeline to mimic the Bidirectional Scattering Distribution Function³ (BSDF) process [157, 158, 159]. This physical-based approach expands Gaussians with a set of additional, learnable appearance parameters (albedo color, roughness, normal vector direction), with the environment lighting modeled as an additional, global texture. This texture, when changed during the rendering, opens the possibility to directly impact the scene lighting (the exemplary pipeline of such a system is presented on Fig. 5). Further works focused on better modeling of indirect lighting. In [160], based on the simple single-bounce ray-tracing the color is sampled either from the global texture or from the set of spherical harmonics trained to model per-Gaussian indirect lighting. Even better effects are achieved after switching to deferred rendering process⁴ [156, 161, 162], allowing for an accurate, per-pixel shading with additional reflection effects, and even adding the explicit point- and directional-light sources [163]. A similar approach with the BSDF pipeline and deferred rendering can be also used with 2DGS [164], providing additional surface-based regularization [165], with extra local mesh reconstruction to achieve better surface quality and reflections [166] To further enhance the quality of surface-lighting disambiguation, some authors utilize multiple different lighting conditions during the training phase. First approaches used single point-light per image [163], and newer solutions require as little as two different global-lighting sets [167]. While the explicit, BSDFbased surface appearance modeling is most popular, there are also attempts to model the view-light-surface dependence using the implicit, trainable latent feature per Gaussian [168]. During the rendering phase, this latent feature is decoded using the light- and view-directions as conditioning inputs.

⁴https://en.wikipedia.org/wiki/Deferred_shading

³A BSDF, or Bidirectional Scattering Distribution Function, is a mathematical model that describes how light scatters when it hits a surface, relating incoming and outgoing light directions and intensities. It's a fundamental concept in physically based rendering (PBR) and is used to simulate realistic material appearances

TABLE III Comparison of main features of different relighting approaches (values for shadows column: RT - ray-traced, AO - baked ambient occlusion)

Method	Dynamic lights	Shadows	Rendering	Representation	
Relightable 3DGS [157]	no	RT	forward	explicit	
GS-IR [158]	yes	RT+AO	forward	explicit	
GaussianShader [159]	no	no	forward	explicit	
GIR [160]	no	RT	forward	explicit	
DeferredGS [161]	no	no	deferred	explicit	
3DGS-DR [156]	no	no	deferred	explicit	
GI-GS [162]	no	RT+AO	deferred	explicit	
GS ³ [163]	yes	RT	deferred	explicit	
GS-ID [165]	yes	AO	deferred	explicit	
Reflective GS [166]	no	RT	deferred	explicit	
ReCap [167]	no	no	forward	explicit	
RNG [168]	yes	RT	deferred	implicit	

Table III presents a comparison of the important aspects of all aforementioned methods.

In the context of a digital twin environment generation, all of the methods lack one, important characteristic. They rely on a single environment map, global for the whole scene. In many indoor scenarios, where we have multiple rooms, each of them is usually different in terms of lighting. This could be addressed by learning per-room environment map and selecting the proper environment during the rendering phase.

B. Mirrors

Fig. 6. Overview of MirrorGaussian [169].

While the approaches presented above are good enough to model the shiny (specular) surfaces, mirrors still pose a challenge for them. Learned environment lighting map is usually of low resolution and can't capture sharp object reflections. In the traditional 3D Gaussian Splatting, the mirror is ignored in the sense that the reflected scene is modeled as another room (if the mirror is on the wall and there are no views from the other side). If the mirror is placed in the middle of a scene, the reflections are usually encoded in the color SH and tend to be very blurry. One of the common approaches to solve this problem is to detect parts of the scene that are actual mirrors and render the scene from virtual camera placed "on the other side" of the mirror [169, 170, 171] (Fig. 6 present a sample rendering pipeline with a single mirror). Those approaches rely on availability of mirror masks in the training dataset (either hand-drawn or detected automatically [172]). The mirror plane

is calculated either on the initial stage from the SfM pointcloud [169] or from the Gaussians created in the first stage of the training from the set of masked input images [170]. The second training step (using full, unmasked images, after fixing the positions of Gaussians) is devoted to the reflection refinement, either by modification of mirror plane [170] or virtual camera position [171]. The natural extension to the presented approaches is to allow semi-transparent reflections (i.e. glass). GlassGaussian [173] expands the Mirror3DGS to work with semi-transparent glass surfaces. The angledependent reflection strength is modeled with an additional spherical harmonics parameter, and the scene is rendered in multiple passes: transparency first, and the mixed with the reflection rendered with the virtual camera. Those approaches allow for the dynamic scenes, as the reflected part f the scene is actually rendered, and not encoded in the Gaussian color parameters (in contrast to [174, 175], which produce good results but only for the static scenes).

IV. TEMPORAL DYNAMICS

A. Temporal dynamics of 3DGS

1) Dynamic scene representation: Different approaches are being adopted in order to represent a dynamic scene in volumetric rendering approaches. Summary of evolution of the representation is given in Fig. 7.

a) Implicit neural representation.: One basic approach use and implicit representation of neural network (mainly MLP) to represent both spatial and temporal axes. In [176] a single network was used to encode both spatial and temporal structure, however sophisticated learnable time encoding using time-invariant latent codes. In [180] the temporal information is embedded into a separate deformation network computing coordinate transformations in time to find mappings in the static canonical configuration represented by different network.

b) Voxel-grid representation.: Implicit approaches are often replaced by more explicit representations using supported voxel-grids. Creating spatio-temporal voxel grids is infeasible due to memory consumption, so usually some hybrid approaches are proposed. In [181] a small deformation network is used to compute point transformations, appropriate

Fig. 7. Evolution of representation methods for dynamic content utilizing differentiable volumetric rendering. The concepts involve fully-implicit representation by neural networks (a), voxel-based 3D representation supported by implicit dynamics (b), fully 4D voxel-based representation using factorization for tractability (c), point-based representation of space (typically by Gaussians) with different methods for representation point dynamics (d). Figure compiled from [176, 177, 178, 179]

positions are sampled from the 3D voxel-grid (representing canonical configuration), but time component is further used in the final radiance network (so the temporal information is in both deformation and radiance networks. Similar approach, but with no explicit deformation field is proposed in [182]. Points at x,y,z coordinates are directly queried in voxel-grids for texture and density to obtain associated features and time component is appended afterwards, before applying radiance field networks. This structure means that some temporal information must be embedded directly into features from texture and density volumes (in addition to radiance networks).

c) Planar factorizations of voxel grids.: Spatio-temporal voxel grids can be approximated from simple structures like planes. In order to maintain compact memory fingerprint the approaches [178, 183] maintain spatio-temporal information in the form of planes (XY,XT,YZ etc.) which can be regarded as 'projections' of the full spatio-temporal voxel grid. The methods differ in representation details. In [178] each matrix element contain a full feature vector independent of its neighbors, while in [183] plane elements are coefficients for a fixed set of basis vector (in the latter cases a number of different basis vectors and different matrices for each plane must be maintained). Grid decomposition into planes can also be used in conjunction with different rendering techniques such as Depth Peeling. In [184] a circural blob is assigned to a voxel grid with learnable radius and density. Learnable features are efficiently obtained via K-planes model. A depth-pealing rendering technique (similar to splatting) is used. Another application of this type of is the modeling of deformation. In [185] the initial set of Gaussians building a scene is modified using data stored in a K-planes model further processed by MLP networks. The Gaussian splatting rendering technique is used.

d) Point-based representations.: Point-based approaches form another category of methods. The scene is typically represented by and unorganized set of Gaussians and different techniques are used to model their temporal dynamics. The Gaussian Splatting technique is used for effective rendering. There are number of approaches that share this characteristic

like [87, 91, 179, 184, 186, 187, 188, 189, 190].

The dynamic models are typically encoded as a deformation field and various approaches are used in this regard. The deformation field can be represented by MLP network [91] sometimes in conjunction with K-planes factorization [185]. In [186] the animation is obtained by modeling variable Gaussian density over time supported by polynomial motion model. Trajectories of individual Gaussians can be encoded on a point-by-point basis [187]. Trajectories can be encoded more efficiently if they are expressed by a limited number of MLPlearnable base trajectories [189] or the dynamic of a dense cloud of Gaussians is represented by a weighed dynamic of a limited set of control points [190], [87] (also MLP driven). A completely different approach was proposed in [188], where in order to represent temporal dynamics, the scene is represented by a set of fully 4D spatio-temporal Gaussians.

e) Decoupling of static and temporal information.: An observed common way to handle a complexity of creating spatio-temporal model is decoupling of storage for static spatial structure (called canonical configuration) and object dynamics. It is often done by specifying a separate deformation function in addition to the structure storing initial spatial information for a static scene. This kind of approach is used in most solutions with some notable exceptions, such as mentioned [176] where only a single network is used for both spatial and temporal information or [188] where the spatio-temporal scene is modeled by fully 4D spatio-temporal Gaussians. Such spatio-temporal Gaussian volume can be projected into an xyz time-slice in order to perform Gaussian Splatting optimization.

B. Regularization of motion patterns

In natural video sequences there exist strong spatio-temporal correlations of the data. More often than not a continuity and smoothness of motion is maintained over a sequence. Situations when an object "apppear out of nowhere" are quite rare. Also the locality of motion is quite common characteristic. The near-by points constituting objects tend to follow similar motion patterns and in short-time windows can be even regarded as rigid objects.

Taking into account typically observed motion constraints can be beneficiary. Having more constraints may result in smaller number of parameters for motion representation and also enable effective learning from much less data. While datadriven approaches using smaller number of spatio-temporal constraints can be effective in multi-camera setups, more model-oriented approaches with stronger constraints are usually better suited for monocular data acquisition.

a) Regularization by representation .: Dynamic scene representation can be a useful tool for ensuring smoothness in spatial and temporal domains. Vanilla 4D voxel-based representation assumes independence of particular voxels. However, 4D voxel-spaces represented as a factorization of simpler structures like planes contain inherent assumption regarding correlations of voxels in out-of-plane directions which represent either spatial or temporal correlations in the data. This property was exploited in approaches based on K-Planes [178, 185] and Hex-Planes [183] representations. This type of explicit modeling of correlations is typically further supported by appropriate loss functions. Different type of representation-based regularization was proposed in [188]. Full 4D Gaussian (spatio-temporal) representation adopted in this solution supports motion smoothness and coherence, providing that Gaussians are enough coarse-grained.

Point-based representations can also be designed in a way to impose some constraints on the motion and introduce certain order to motion estimation. Good examples are approaches that base on projecting individual motion patterns on a small number of learnable template motion trajectories (called motion representation fields) [189]. Due to per-point sharing of base trajectories, the method is provide constraints to the motion field leading to faster and more reliable optimization. Similar goal is achieved in related approaches [87, 190] where templates are formed by a small subset of control points, for which trajectories are established by a trainable neural network, while the positions and rotations of Gaussians in time are governed by near-by control points using Linear Blend Skinning principle.

b) Regularization loss functions.: Another, and more general way to impose constraints and smoothness on motion is by applying custom loss functions during training. One approach is the regularization imposed on the features stored in grid-like representation. In [178] the K-Planes representation of spatio-temporal volume is accompanied by apppropriate regularization losses. While Total Variation in Space component of the loss is responsible for ensuring smoothness in spatial dimensions, a special Smoothness in Time component is established specifically for the temporal dimensions. This component is in the form of 1-D Laplacian in order to prevent fast accelerations in time domain.

The approaches based on Gaussian representation as intrinsically less constrained are often subject to regularization loss functions. In order to obtain good tracking properties of the system the authors of [187] introduce 3 auxiliary loss functions in addition to the standard image reconstruction error: the local rigidity of motion in short time window, similarity of near-by Gaussians' rotations in short time window and the long-term isometry loss preventing near-by Gaussians to drift apart over longer time intervals.

While representation of motion by a superposition of limited number of trajectories [189] or the motion of limited number of control points [190], [87], imposes certain constraints on motion patters, it can be further extended by appropriate loss functions. E.g. in [189] two additional loss functions are introduced to ensure that arbitrary point trajectory is not dependent on too many template trajectories. Also, the rigidity of motion is supported by the loss enforcing nearby points to have similar trajectory coefficients. In [190] ARAP (As Rigid As Possible) principle is used to achieve similar goals. First a rotation matrix is estimated that best superimpose two temporal configurations of near-by points, then the (ARAP) loss function computes distance errors for this superimposition.

C. Efficiency considerations of temporal methods

The temporal modeling methods based on NeRF, due to increased size of input data, suffer from even greater performance hit then their static counterparts. The time required to train for the network in [180], [176] is measured in days and single frame inference in dozens of seconds. A part of this computational inefficiency originates from the complexity of implicit representation of density and color by a neural network. More recent approaches use voxel grid to explicitly encode at least spatial structure of the scene [177, 181, 182]. This representation enables performance of fast spatial queries and significantly reduce training time below 1h on DNerf dataset [180] (except for [182] where the training takes several hours) and inference time to order of magnitude about 1s (or even less [177] when filtering static parts of the scene).

The concept of voxelization of the representation is further enhanced into a fully spatio-temporal modules, [178, 183, 184]. For memory tractability such volumes are usually represented using factorization into simpler structures (e.g. 2D matrices). Such solutions [183],[178] give comparable or better training times (dozens of minutes on simpler datasets [180] or several hours on more complex datasets [176]). When paired with efficient rendering technique (hardware-supported differentiable depth-peeling) even real-time rendering performance can be achieved [184].

Gaussian splatting rendering technique provides a boost to the rendering as well as training speeds. This category of methods is able to achieve times below 1h even on complex datasets and a real-time rendering speed [91, 185, 186, 189] with several methods easily surpassing 100 fps.

D. Applicability of temporal methods in robotics

There are several qualities that can be found important for applicability of scene reconstruction method in robotics. 1) the method efficiency, so the methods can work real-time at the inference stage and at least near-real-time at learning stage, 2) ability to work on a sparse set of cameras (ideally in monocular setup), 3) ability to track scene points.

 TABLE IV

 Datasets related to articulated objects or scenes with statistics.

	Source	Clean mesh	Scene-level	Image	Appearance	# categories	# objects	# articulated parts
RPM-Net [191]	synthetic	1	×	x	X	43	969	1,420
Shape2Motion [192]	synthetic	1	×	X	×	45	2,440	6,762
PartNet-Mobility [193]	synthetic	1	×	X	1	46	2,346	14,068
AKB-48 [194]	real	1	×	X	1	48	2,037	-
OPDReal [195]	real	×	×	1	1	8	284	875
MultiScan [196]	real	×	1	1	1	20	10,957	5,129
GAPartNet [197]	synthetic, real	1	×	X	1	27	8,489	1,166
ACD [198]	synthetic	1	×	×	1	21	354	1,350

Regarding the first point, the most recent methods based on Gaussian Splatting such as [91, 185, 186, 189] seem to currently offer the highest speed in rendering (over 100 fps) but also in training. These methods are iterative, so they can be safely stopped before a full convergence to quickly obtain a map with lower level of details.

The ability to work on a sparse set of cameras is not always explicitly discussed in the papers regarding the topic. The structure of both NeRF and GS-based methods are based on multi-view optimization does not inherently define the number of required camera inputs, however some methods may be more suitable than the others for monocular environment. One of the commonly evaluated monocular dataset is DNeRF [180]. Most of the prominent GS methods were evaluated on this dataset [91, 179, 185, 188, 189, 190].

The methods evaluated in multi-camera setups are e.g. [184, 186, 187]. Since single camera setups induce less input data, the methods handling monocular inputs often put pressure on applying motion regularization techiques like control points [179, 190], shared motion trajectories [189], 4D Gaussians [188] or deformation field factorization [185].

Point 3) - the ability to track scene points is important from the perspective of estimating object motion and articulation in a dynamic scene. While most GS splatting methods due to particle-like structure of the scene this ability is expressed naturally, there are some approaches like [179, 187, 189, 190] the incorporate the objective of tracking more explicitly and incorporate strong regularization on Gaussian particle motion. While most GS solutions assume the motion field affecting Gaussian position, size and orientation, there is a notable exception [186] where also opacity is subject to a temporal change (which gives an effect of appearing and disappearing Gaussians over time). While the latter approach is good for animation and rendering it might not be effective for tracking.

E. Articulated parts of objects

Articulated objects, composed of multiple rigid parts connected by joints, encompassing a wide range of objects, such as human bodies, mechanical assemblies, furniture, etc. The reconstruction or generation of articulated objects aims to comprehend and represent the shape and mobility of articulated components.

Articulated object reconstruction. The goal of articulated object reconstruction is to recover the 3D geometry and motion

parameters of the objects from various observations. The challenges involve decomposing the part into articulated components and producing the reconstructed surface that can be animated into different articulation states. The input modalities include point clouds, multi-view RGB or RGB-D images, and RGB videos. A line of work focuses on reconstructing the whole object as a single deformable surface either over time or given different states [199, 201, 202, 203, 204, 205]. Another line of work reconstructs each part as separate surfaces interconnected by joints to enable articulation [206, 207, 208, 209, 210].

A-SDF [202] was the first to reconstruct articulated objects using signed distance fields from a single snapshot, allowing deformation into different articulation states. [203] share the same goal with A-SDF but take multi-view RGB images as input for the reconstruction, while CARTO [199] further extends the input to a single stereo RGB image. These works assume the object has only one movable part. LEIA [205] reconstructs the interpolated state of the object between the two given input states from multi-view images without knowing the number of moving parts. These works reconstruct the articulated object as a single unified surface or as an implicit deformation field. The lack of part-level structure in the output geometry makes it difficult to be simulated in a physical simulation software.

To address the part-level reconstruction, CLA-NeRF [206] proposes to reconstruct the object from a few multi-view RGB images of an unseen 3D object instance within the known category. It assumes that the object category is known and all the instances in the category share the same articulated structure. To avoid the reliance on object category, Ditto [207] reconstructs from a pair of point clouds, while PARIS [208] take multi-view RGB images observing the object in two states as input. [209] extends the setting of PARIS to multi-view RGB-D images and reconstruct multiple articulated parts in the output. These works assume the number of articulated parts is known at inference time. In a more flexible setting, Real2Code [210] proposes to reconstruct articulated parts from multiple unposed RGB images of the object in an opening state, and focuses on certain categories of objects that mostly have cuboid-like parts but with no assumption on the number of articulated parts.

Articulated object generation. This line of work aims to synthesize the articulated objects in both geometric and kinematic structures from random noise or user-specified con-

13

Fig. 8. Summary on articulated object reconstruction from different visual input. Figure reproduced from original paper [134, 199, 200, 201].

straints. NAP [211] is a pioneering work that generates a full description of the articulated object, including part geometry, articulation graph, and joint parameters from random noises unconditionally. CAGE [212] extends the task in a conditional setting, where the object category and a part connectivity graph as given as the user-driven input. The output of these works targets the mesh repre- sentation composited in varied structures. SINGAPO [134] and ArtFormer [213] further introduce different controllable generation setting where SINGAPO enables single-image-conditioned generation, and ArtFormer focuses on text-driven generation. ARTICULATE-ANYTHING [214] proposes a general framework that automates the articulation of objects from different input modalities, including text, images, and videos. Programs are used to arrange the part geometries and predict articulation with a specialized mechanism designed to ensure the plausibility of the generated object.

SINGAPO [134] is focused on generation of articulated parts of household object from a single image, like refrigerators, cabinets, or microwaves. The pipeline consists of three progressive steps: Inferring the part connectivity graph from the image using GPT-40 models with in-context learning to predict the connectivity graph of articulated parts from the input image; Structuring the parts using a graph with masked attention of transformer-based diffusion model; Collecting meshes from a part shape library to assemble the final object based on the outputs from previous steps.

V. EXTRACTING PHYSICAL PROPERTIES FOR AVAILABLE SIMULATORS

Extracting physical properties from videos to utilize in physics simulations is a critical step in creating an accurate digital twin. This chapter examines the essential elements needed to accurately simulate a scene within a physics-based environment [5]. We start by summarizing the most popular and recent simulation software across various domains, ranging from simple physical scenes with just rigid bodies and contact interactions to more complex situations involving multi-joint bodies, from soft bodies to fluid dynamics. The chapter investigates how characteristics such as mass, inertia, friction, and viscosity can be derived from video data into a scene description or 3D Gaussians.

Recently, physics simulations have seen significant improvements, becoming faster, more reliable, and more comprehensive. They now span a wide array of applications in robotics, industry, and healthcare. This subsection examines the most advanced and widely-used simulation technologies, along with their scene description format. This will highlight the expected outcomes of the video data necessary to accurately create a digital twin.

1) State-of-the-art Simulation Technologies: According to [215], the leading physics engines for robotics applications as of September 6, 2023, ranked by frequency of publication, are MuJoCo [216], Gazebo [217], PyBullet [218], Webots [219], and Brax [220]. These engines are optimized for performance, focusing primarily on the dynamics of rigid bodies and multijoint systems, and support both URDF and MJCF formats. They are widely used in physics-based reinforcement learning research.

For soft body simulations, especially in medical contexts, SOFA [221] stands out. It offers high modularity through customizable modules and libraries, facilitating complex interactions such as cutting [222] and manipulating soft arms [223]. SOFA employs Finite Element Methods (FEM) and requires a meshed discretization of simulated objects. It uses a scene graph structured as a Direct Acyclic Graph for scene importation, detailing mechanical properties and numerical tools, but does not support URDF or MJCF conversions.

ProjectChrono [224] excels in particle simulations and granular dynamics, particularly supporting vehicle simulations for both wheeled and tracked vehicles. It uses the Discrete Element Method (DEM) to simulate large granular systems efficiently on GPUs. ProjectChrono organizes its scenes in JSON format and includes an URDF parser, with the US Army employing it for vehicle simulations.

In the realm of photo-realistic graphics engines, Isaac Sim [225], Unreal Engine, Unity [226], Godot, and Blender [227] are recognized for their high-fidelity visual rendering. Isaac Sim, developed by NVIDIA, utilizes PhysX for physics simulation and is tailored for robotics reinforcement learning. Unreal Engine and Unity, primarily game engines, also find applications in robotics, with implementations like CARLA [228], URoboSim [229], and RoboKudo [230]. Unity further enhances its capabilities by supporting MuJoCo as a physics plugin. Most of them support importing scene from USD format.

Depending on the specific application domains, multiple

physics simulations can be utilized. Recently, Genesis [231] has integrated multiple physics solvers and their interactions into a cohesive system. It features a modular design that includes several generative modules, each dedicated to processing different data modalities, all orchestrated by a high-level agent.

Each simulation platform offers unique advantages and limitations that directly impact the effectiveness of algorithms tailored for specific applications. Algorithms focused on perception benefit from simulators with photo-realistic rendering capabilities, whereas those involved in physics control require simulators that provide detailed APIs for dynamics control, like applying joint torques or forces. For more complex simulation tasks, such as cutting or pouring, the use of FEM or DEM is crucial.

2) Scene Description Formats: A robotic scene description is a file format used to describe the configuration of a scene for simulation purposes. Typically, each simulation software employs its own specific scene description format [232], such as MJCF for MuJoCo, SDF for Gazebo, and PROTO for Webots... (see Figure 9). This variety can lead to compatibility issues when a scene described in one format needs to be simulated in a different software environment. As a result, URDF has become widely adopted as a standard format for importing rigid and multi-joint bodies [233]. However, URDF is limited to modeling rigid bodies with only basic constraints and lacks support for complex dynamics such as damping and friction. As a result, it is not suitable for representing soft bodies or fluids. Additionally, URDF does not include photorealistic rendering features for camera simulations; it is primarily intended to define a robot's visual appearance and collision models using standard joint types.

Fig. 9. Different simulators and their scene descriptions, generated from a real environment

To address the limitations of URDF in depicting more complex scenes that include photorealistic rendering properties, the Universal Scene Description (USD) [234] has recently been introduced as a standard format for scene descriptions. Developed by Pixar, USD forms the backbone of Pixar's 3D graphics pipeline and is utilized in every 3D authoring and rendering application. Originally used in animation studios, USD can describe various domains, including rigid bodies, soft bodies, and fluids. It is the only format that can be extended and customized through the creation of new schemas. In the field of robotics, this format has received robust support and enhancements from NVIDIA Omniverse and its robotics extension, Isaac Sim, by integrating properties for the PhysX physics engine. Numerous parsers have been implemented to convert different formats into USD and vice versa, making USD a flexible and valuable format for describing complex scenes with photorealistic properties. Research efforts utilizing USD include studies that translate scene descriptions into knowledge graphs [235], the compilation of datasets containing real-world indoor scenes with annotated semantic segmentations [236], and the creation of neuro-symbolic representations of 3D scenes [237].

B. Learning physics-based attributes from videos

The choice of physics engine depends on the specific physical phenomena being modeled, as different engines offer varying features and support different physics parameters in their scene descriptions. Table V presents a brief comparison of simulators and their supported scene description formats. By selecting an appropriate simulator, one can encode the estimated physics parameters from an algorithm into the scene description and load them directly into the simulation environment.

For the rigid bodies aspect, object mass and friction can be estimated by aligning physics engine simulations with visual observations through methods like Markov Chain Monte Carlo (MCMC) [241]. Galileo [242] leverages this approach by using short MCMC runs to infer latent physical properties—such as mass, shape, and friction-based on how well the simulated outcomes match key features in video input. Additionally, the model incorporates deep learning to learn a direct mapping from visual data to physical parameters, effectively inverting part of the generative process for faster and more efficient inference. Another approach [243] estimates physical properties from video by combining a physics engine with a correction estimator. The system simulates object behavior from the initial state and refines parameters by comparing simulated and observed outcomes. It supports non-differentiable physics engines and uses either optimization techniques or neural networks for correction, showing robust performance in 2D bin scenarios.

In the context of soft body simulation, particularly cloth simulation, a deep learning-based approach [244] estimates cloth stiffness directly from video and applies it to virtual environments. This method leverages a Transformer architecture combined with pre-trained models such as ResNet50 [245] and VGG16 [246] to classify cloth behavior based on softness-to-stiffness labels. Trained on a dataset of 3840 videos, the model achieves an average accuracy of 99.5%, significantly outperforming traditional sequence models like RNNs, GRUs, and LSTMs. Another approach [247] passively estimates fabric stiffness and area weight by analyzing motion in videos under unknown wind forces. Using video texture features and a regression model, it accurately predicts material properties, validated against a ground truth dataset and human perceptual studies.

TABLE V Simulators Comparison Table

	Scene Description		
	Fc	ormats	
	Main Compatible		Outstanding features
MuJoCo [216]	MJCF	URDF	Fast and accurate physics for continuous control with smooth contact dynamics; great for reinforcement learning; used in research; Url: https://mujoco.org
Gazebo [217]	SDF	URDF	Modular and ROS-integrated; supports realistic sensor simulation; suitable for real-world robot prototyp- ing; large plugin support; Url: https://gazebosim.org
PyBullet [218]	BULLET	SDF URDF MJCF	Easy scene prototyping with ML support; integrates OpenGL rendering for lightweight digital twin visualization; Url: https://pybullet.org
Webots [219]	PROTO	URDF	Fast setup of indoor environments with GUI and rich built-in robot/sensor models; User-friendly GUI; good for education; Url: https://cyberbotics.com
Drake [238]	MJCF	URDF	Analytical control modeling with structured dynamics; great for optimization in constrained spaces; Url: https://drake.mit.edu
SOFA [221]	SCN		Real-time soft-body simulation and surgical interaction modeling for indoor scenarios; Url: https://www.sofa-framework.org
Project Chrono [224]	JSON	URDF	Simulates rigid/flexible bodies, fluids, and granular materials; advanced multibody physics; Url: https://projectchrono.org
Omniverse [239]	USD	MJCF URDF	GPU-accelerated and photorealistic rendering; built for robotics digital twins with Isaac Sim; Url: https://www.nvidia.com/en-us/omniverse/
Unreal Engine	UASSET	USD	High visual fidelity, immersive VR/AR support, and accurate physics for indoor scene interaction; used for robotics, games, architecture; Url: https://www.unrealengine.com
Unity [226]	YAML		Fast-prototyping; cross-platform; ML and robotics integration via Unity Robotics Hub; Url: https://unity. com
Godot [240]	TSCN		Open-source and customizable; good for simple 3D/2D simulations; low resource use; Url: https://godotengine.org
Blender [227]	BLEND	USD	High-quality asset creation and scripting for synthetic data generation in robotics pipelines; large graphics community; Url: https://www.blender.org
Genesis [231]	USD	URDF MJCF	GPU-accelerated simulation with built-in generative tools for photorealistic indoor robotics datasets; Url: https://genesis-embodied-ai.github.io

In the context of fluid dynamics, viscosity is a key property that is typically measured using manual and time-consuming techniques. A recent method [248] employs 3D convolutional neural networks to estimate viscosity from videos of fluid motion recorded by a robotic system. By analyzing spatiotemporal patterns, the model predicts viscosity and fluid types with greater accuracy than human observers, supporting more efficient automated experimentation.

In summary, recent advances demonstrate that physical properties of rigid bodies, soft bodies, and fluids can be effectively estimated from visual data using a combination of simulation, optimization, and deep learning. These approaches enable automated and non-invasive inference of properties like mass, stiffness, and viscosity, supporting more accurate and efficient physical scene understanding across various domains.

C. Introducing physical properties in 3DGS representations

Various studies have utilized images and video data to drive generative dynamics using a 3D Gaussian approach. This method eliminates the need for traditional geometric constructs such as triangle/tetrahedron meshing, marching cubes, "cage meshes," or other forms of geometry embedding. A novel technique, PhysGaussian [249], has been developed to integrate physically grounded Newtonian dynamics within 3D Gaussians seamlessly, facilitating high-quality novel motion synthesis. This method uses a customized Material Point Method (MPM) that enhances 3D Gaussian kernels with physically significant kinematic deformation and mechanical stress attributes, all governed by the principles of continuum mechanics. A key feature of this method is its smooth integration of physical simulation and visual rendering, where both components share the same 3D Gaussian kernels for their discrete representations.

This chapter explored the process of extracting physical properties from visual data to enable realistic and accurate physics-based simulations, which are essential for building digital twins. We reviewed widely used simulation engines across domains-rigid, soft, and fluid-and examined how their scene description formats influence integration and fidelity. Traditional formats like URDF offer basic support for rigid bodies but lack flexibility for complex dynamics, while newer formats like USD provide extensibility and support for photorealistic scenes. Advances in simulation, deep learning, and optimization now allow for the non-invasive estimation of physical parameters from video, making it possible to directly translate real-world observations into simulation-ready data. Emerging methods like 3D Gaussian representations further unify geometry, physics, and rendering into a compact, datadriven framework, pointing toward the future of simulationbased digital twin systems.

VI. DATASETS

A. Simultaneous Visualization of 3DGS and Mesh Models

The following options are capable of visualizing both **3D Gaussian Splatting (3DGS)** and traditional **mesh models** simultaneously:

- 1. NVIDIA Omniverse. Supports USD format, allowing integration of both 3DGS (via custom rendering) and meshes. Compatible with NeRF-based techniques like Gaussian Splatting.
- 2. Blender (with Add-ons). Blender's shader nodes and geometry nodes can be used to load and render 3DGS data. Mesh rendering is natively supported. Requires a plugin like 3DGS Blender Addon (custom implementation might be necessary).
- **3. Unreal Engine (UE5).** Can handle 3D Gaussian Splatting via custom shaders or plugins. Natively supports mesh rendering.

B. Scene datasets

TABLE VI Summary of data modalities in selected scene datasets (X: available, 0: partial)

Name	Туре	RGB frames	Depth	Panorama	Mesh	Texture	Semantic segm.	Instance segm.	Articulated objects	[
Replica [250]	scan				х	x	х	х]
ReplicaCAD [251]	model				x	x	0	0	X][
Matterport3D [252]	scan	x	x	x	х	x	х	х]
Matterport for Habitat	scan				х	x	0	0]
HSSD-200 [253]	model				х	x	х	х		1
iThor dataset [254]	model				х	x	х	х	X	ا [
ProcTHOR [255]	model				х	x	х	х	x	1
Gibson Dataset [256]	scan	x			х	x	х			1
3D-FRONT [257]	model				х	x	х	х		1
ScanNet++ [258]	scan	x	x		х	x	х	х]
