Abstract

Speculative decoding accelerates large language model inference using a smaller draft model. In this paper, we establish a surprising connection between speculative decoding and channel simulation, which aims at simulating a noisy channel using as few bits as possible. This connection allows us to provide an information-theoretic analysis of the speed up that can be achieved by speculative decoding. Leveraging this link, we derive an explicit relation between generation speed-up and the number of tokens k generated by the draft model for large k, which serves as an upper bound for all k. We also propose a novel speculative decoding method via exponential races ERSD that matches state-of-the-art performance.

1 Introduction

Transformer-based large language model (LLM)s are at the forefront of the AI revolution, driving rapid advancements across numerous applications. However, as their adoption accelerates, the speed of text generation emerges as a critical bottleneck, alongside compute and memory constraints. Standard LLM generation involves calculating the conditional probability distribution using the target model P given a partial output $x_{:n} = (x_1, x_2, ..., x_n)$, which is the concatenation of the initial context and all previously generated tokens. The target model P outputs the conditional probability distribution $P(\cdot \mid x_{:n})$, from which a single token x_{n+1} is sampled and concatenated to $x_{:n}$ to form the updated sequence $x_{:n+1}$. These steps are repeated iteratively until a stopping condition is met, such as reaching a maximum sequence length or generating an end-of-sequence token. This autoregressive token-by-token approach inherently leads to slow generation speeds. Speculative decoding accelerates this process by potentially generating more than one token for each

target model P evaluation, while guaranteeing the same output quality—that is, the distribution of generated text remains identical to standard autoregressive decoding. It consists of the following three steps:

- 1. **Drafting**—a smaller draft model Q is used to generate one or more possible continuations of the token sequence $x_{:n}$; this may involve multiple sampling calls of the draft model.
- 2. **Evaluation** the target model *P* evaluates all drafted continuations in parallel.
- 3. **Verification** one or more tokens are accepted, based on their probabilities under Q and P.

Speculative decoding achieves a $2-3 \times$ speed-up in text generation (Leviathan et al., 2023; Chen et al., 2023). Following common computational models, we quantify speed-up as the expected number of generated tokens per evaluation of the target model P. For a fair comparison of different speculative decoding strategies, we fix the number of drafted tokens k and analyze the speed-up achieved. Channel simulation is a compression problem focused on efficiently generating samples from a target probability distribution P at a decoder (Li, 2024). While only the encoder knows the target distribution P, both the encoder and decoder can access to samples from common reference distribution Q. Unlike standard source coding, the goal is not to communicate a specific sample, but rather to ensure that the decoder can generate any sample distributed according to P. Common methods rely on generating a shared codebook (list) of samples at the encoder and decoder. Based on the target distribution P, the encoder communicates to the decoder an index from this list, guaranteed to follow the target distribution P. A good introduction is provided by Theis and Yosri (2022), and Li (2024) compiles a

Figure 1: Speculative decoding trees: a black draft tree overlaid with a green/red GSD decision tree. Black vertices and arrows represent the draft tree; each vertex is a drafted token, and paths from the gray root are potential text continuations. Green/red arrows show GSD acceptance/rejection decisions. Blue leaf vertices signify sampling from a distribution. (Note: ERSD does not follow the same decision tree.)

comprehensive literature review. Intuitively, both speculative decoding and channel simulation aim to generate samples from some target distribution P by generating samples from a draft/reference distribution Q. In channel simulation, the goal is to minimize the entropy of the chosen index. In speculative decoding, the goal is to maximize the probability of one of the drafted tokens being accepted. Although these objectives seem different, the most common speculative decoding method (Leviathan et al., 2023; Chen et al., 2023), which we refer to as greedy speculative decoding (GSD), (explained in the next section as a batch drafting strategy), and a channel simulation method called greedy rejection sampling (Harsha et al., 2010; Flamich and Theis, 2023) are essentially the same procedures! To explain this surprising connection, we develop a theory that explicitly links the entropy of the accepted token with the speed-up of speculative decoding by considering the generation of multiple tokens. Additionally, we propose a novel speculative decoding strategy, exponential race speculative decoding (ERSD), based on another channel simulation method called Poisson functional representation (Li and El Gamal, 2018). We demonstrate that its performance matches that of GSD. Our contributions in this paper are:

- Establish a surprising connection between speculative decoding and channel simulation.
- Propose a new speculative decoding method using Poisson functional representation.
- Derive an explicit relation between the num-

ber of drafted tokens and the expected number of accepted tokens, i.e., the speed-up of response generation.

Throughout this paper, Ω denotes the finite set of tokens, where each token is represented by an integer corresponding to a textual element. Sets are enclosed in braces $\{\}$, sequences in parentheses () and concatenation of sequences a and b is written as a||b.

2 Speculative decoding

LLMs predict the distributions of tokens conditioned on the preceding sequence. We can consider an LLM as a black box that takes a sequence of tokens $x_{:n}$ as input, and outputs a set of distributions $\{P(\cdot \mid x_{:i})\}_{i \leq n}$. In standard autoregressive decoding, we typically utilize only the last distribution $P(\cdot \mid x_{:n})$ to sample the next token. In contrast, speculative decoding leverages distributions conditioned on different subsequences to accelerate generation. The simplest case of GSD, is outlined in Algorithm 1. In the drafting stage (lines 2-3), a single token \tilde{x} is generated using the draft model Q, we dub this *simple* drafting strategy. Subsequently, in the evaluation stage (line 4), the target model processes the sequence $x_{:n}||(\tilde{x})$ and produces, among others, two relevant distributions: $P(\cdot \mid x_{:n})$ and $P(\cdot \mid x_{:n}||(\tilde{x}))$. The verification stage then determines whether to accept \tilde{x} based on probabilities of both $P(\cdot \mid x_{\cdot n})$ and $Q(\cdot \mid x_{:n})$. If \tilde{x} is accepted, the algorithm effectively generates two tokens per target model evaluation, as $P(\cdot \mid x_{:n}||(\tilde{x}))$ is already com-

Algorithm 1 Simple GSD (k = 1)

```
1: Input: partial output x_{:n}, draft model Q, target model P

2: EVALUATE(Q, x_{:n})

3: \tilde{x} \sim Q(\cdot \mid x_{:n})

4: EVALUATE(P, x_{:n} \mid \mid (\tilde{x}))

5: U \sim \text{Uniform}(0, 1)

6: if \frac{P(\tilde{x} \mid x_{:n})}{Q(\tilde{x} \mid x_{:n})} > U then

7: x_{2}^{next} \sim P(\cdot \mid x_{:n} \mid \mid (\tilde{x})))

8: Return (\tilde{x}, x_{2}^{next})

9: end if

10: P_{residual} \leftarrow \max(P(\cdot \mid x_{:n}) - Q(\cdot \mid x_{:n}), 0)

11: P_{residual} \leftarrow P_{residual}/\text{SUM}(P_{residual})

12: x_{residual} \sim P_{residual}

13: Return (x_{residual})
```

puted and can be sampled from. Otherwise, if \tilde{x} is rejected, the algorithm performs a standard autoregressive step, but samples from a residual distribution $P_{residual}$ derived from $P(\cdot \mid x_{:n})$ and $Q(\cdot \mid x_{:n})$. This residual distribution focuses on sampling from tokens to which the target model P assigns proportionally higher probability than the draft model Q. A straightforward extension to the *simple* drafting strategy is to speculate a *sequence* of k tokens instead of just one. During the **drafting** stage the draft model Q is run autoregressively k times to generate a draft sequence of length $k, (\tilde{x}_{(1)}, \tilde{x}_{(1,1)}, \dots, \tilde{x}_{(1)_{i-1}^k}).$ The notation \tilde{x}_i describes that the token at position $\mathbf{j} = (j_1, \dots, j_{m-1}, j_m)$ comes after $\tilde{x}_{\mathbf{j}'}$ where $\mathbf{j'}=(j_1,\ldots,j_{m-1})$. The evaluation step then processes the entire drafted sequence $x_{:n}||(\tilde{x}_{(1)},\tilde{x}_{(2)},...,\tilde{x}_{(k)})$ in parallel using the target model P. The drafted tokens are then verified and accepted sequentially, starting from the first, until a rejection occurs or all k drafted tokens are accepted. Consequently, the sequence strategy can generate from 1 to k+1 tokens per evaluation of the target model P. An alternative to sequence drafting is batch drafting (Sun et al., 2024), where multiple candidate continuations are explored. Specifically, Q is evaluated once to sample multiple draft token alternatives, which are then evaluated in parallel by the target model P. While naively computationally intensive, Miao et al. (2024) showed that it can be done at the same computational cost as sequence drafting.

Algorithm 2 Simple ERSD (k = 1)

```
1: Input: partial output x_{:n}, draft model Q, target model P

2: EVALUATE(Q, x_{:n})

3: for all i \in \Omega do

4: e_i \sim \operatorname{Exp}(1)

5: end for

6: \tilde{x} \leftarrow \arg\min_{i \in \Omega} \frac{e_i}{Q(i|x_{:n})}

7: EVALUATE(P, x_{:n} || (\tilde{x}))

8: x_1^{next} \leftarrow \arg\min_{i \in \Omega} \frac{e_i}{P(i|x_{:n})}

9: if \tilde{x} = x_1^{next} then

10: x_2^{next} \sim P(\cdot \mid x_{:n} || (\tilde{x}))

11: Return (\tilde{x}, x_2^{next})

12: end if

13: Return (x_1^{next})
```

¹ This yields distributions $(P(\cdot \mid x_{:n} || (\tilde{x}_{(i)})))_{i \le k}$. The verification stage then sequentially considers each drafted token $\tilde{x}_{(i)}$ until the first acceptance. This strategy generates two tokens if any drafted token is accepted, or one if all get rejected. To avoid redundancy, candidates should be sampled without replacement (Jeon et al., 2024). To recall the connection highlighted in Section 1, the acceptance criterion in greedy rejection sampling and batch GSD when $k = |\Omega|$ is exactly the same. The *tree* drafting strategy, which subsumes *simple*, sequence, and batch methods, operates on any ordered tree topology. Each vertex represents a token drawn from Q. Each path from the root to a leaf constitutes a possible sequence drafted autoregressively. The general tree GSD algorithm, detailed in Appendix A and Algorithm 4, recursively applies batch selection at each vertex of the tree to generate the accepted sequence. All the strategies are illustrated in Figure 1. The work most closely resembling ours is Chen et al. (2025), which investigates optimal tree topologies for GSD under specific assumptions. Our analysis is more general and encompasses their problem setting as a special case. Moreover, by establishing connections to information theory – specifically channel simulation (Li, 2024) and Tunstall coding (Tunstall, 1968) we derive an upper bound on the expected speed-up, which converges when the number of drafted to-

 $^{^1}$ A straightforward implementation of *batch* drafting would require evaluation of k sequences of length (n+1), but this can be reduced to a single sequence of length (n+k) by manipulating attention masks and token embeddings – resulting in the same cost as *sequence* drafting.

kens k is large. Additionally, our algorithm for generating decoding trees achieves $O(k \log k)$ complexity, outperforming the $O(k^2 |\Omega|)$ complexity of Chen et al. (2025). Additionally, we consider token-by-token generation, unlike global generation (Hu and Huang, 2024) which operates on trees natively.

3 Exponential Races

An exponential race (Maddison, 2017) is a Poisson process with time-ordered points, each corresponding to a sample from a distribution P. We are interested in the winner (first point) of this race. In the discrete case, we can simulate relevant points, i.e., potential winners, by associating each element i of the sample space Ω with an exponential random variable $e_i \sim \text{Exp}(1)$, $\mathbf{e} = \{e_i\}_{i \in \Omega}$. The winner of the race, $i^* = \arg\min_{i \in \Omega} \frac{e_i}{p_i}$, is distributed according to $i^* \sim P$. This is also known as the Gumbel-max trick (Jang et al., 2017), where arrival times are obtained via the monotonic transformation $-\log(\cdot)$. Thus, given a distribution P, exponential races allow us to sample from it using independent exponential random variables. Let P and Q be distributions with the same support Ω . Using the same realization of e for exponential races yields $i_P^* = \arg\min_{i \in \Omega} \frac{e_i}{p_i} \sim P$ and $i_Q^* = \arg\min_{i \in \Omega} \frac{e_i}{q_i} \sim Q$, both following their respective distributions. If P and Q are similar (i.e., the ratio $\frac{p_i}{q_i}$ is close to 1), then it is likely that $i_P^* = i_Q^*$. An example is illustrated in Figure 2, where Q and P are distributions generated by LLMs. The simplest version of ERSD is presented in Algorithm 2, where only a single token is generated from the draft model in the drafting stage: a winner of an exponential race under $Q(\cdot \mid x_{:n})$. As in GSD, the target model P is then **evaluated** on the sequence $x_{:n}||(\tilde{x})$. During **verification**, if the winner of the exponential race under $P(\cdot \mid x_{:n})$ is also \tilde{x} , one more token is drafted. It is straightforward to extend this approach to a *sequence* strategy, by generating an exponential race for every node in the draft sequence. For the batch strategy with k alternatives, the drafted tokens are selected as the first k arrivals of the exponential race under the draft model Q, as those are the most likely winners of the race under law P. Like the traditional GSD, the batch case can be generalized to the full tree by continuing different trajectories. The general procedure for this tree approach is presented in Appendix A as Algorithm 5. Standard GSD prioritizes maximizing the probability of accepting the initially proposed draft token. Indeed, for the *simple* (and thus, *sequence*) drafting strategy, greedy decoding achieves optimality within token-based speculation (Sun et al., 2023), with the acceptance probability given by $1 - D_{TV}[P(\cdot \mid x_{:n}), Q(\cdot \mid x_{:n})]$, where $D_{TV}[P,Q] = \frac{1}{2} \sum_{i \in \Omega} |P(i) - Q(i)|$ is the total variation distance (Csiszár and Körner, 2011). We can establish a corresponding bound for the acceptance probability of the first drafted token in ERSD using the Poisson matching lemma (Li and Anantharam, 2021).

Lemma 3.1. For ERSD with target distribution $P = P(\cdot | x_{:n})$ and draft distribution $Q = Q(\cdot | x_{:n})$, the probability of accepting the first drafted token, $P_{accept}^{(1)}$, satisfies:

$$1 - D_{TV}[P, Q] \ge P_{accept}^{(1)} \ge D_{HM}[P, Q],$$
 (1)

where D_{HM} denotes the harmonic mean distance, defined as:

$$D_{HM}[P,Q] \stackrel{def}{=} \sum_{i \in \Omega} \frac{P(i)Q(i)}{P(i) + Q(i)}.$$
 (2)

The proof Lemma 3.1 is shown in Appendix B. Despite a lower first-token acceptance probability, exponential races are not inferior to greedy decoding. As we will show, the overall performance for both methods hinges on the entropy of the acceptance distribution. From a channel simulation perspective, this entropy is linked to the Kullback-Leibler (KL) divergence between P and Q.

4 Markov Chain Simulation

The question we are trying to answer in this section is: what is the best drafting strategy, i.e., what drafting tree is optimal? In such a tree, each vertex, except the root, is associated with a drafted token. Specifically, for a vertex indexed by $\mathbf{j} = (j_1, \ldots, j_l)$, the associated token $\tilde{x}_{\mathbf{j}}$ is sampled from $Q(\cdot \mid x_{:n} || (\tilde{x}_{\mathbf{j}:1}, \ldots, \tilde{x}_{\mathbf{j}:l-1}))$, where $\mathbf{j}_{:m} = (j_1, \ldots, j_m)$. Let $R(\mathbf{j} \mid x_{:n})$ denote the probability that vertex \mathbf{j} , and thus the drafted token $\tilde{x}_{\mathbf{j}}$, is accepted during verification, given the context $x_{:n}$ and a chosen speculative decoding algorithm. $R(\mathbf{j} \mid x_{:n})$ is defined as the probability of acceptance, marginalized over all possible draft token sequences from Q:

$$R(\mathbf{j} \mid x_{:n}) = \underset{\tilde{x} \sim Q(\cdot \mid x_{:n})}{\mathbf{E}} \mathbf{Pr} \left\{ \tilde{x}_{\mathbf{j}} \text{ accepted } \mid x_{:n}, \tilde{x} \right\}$$
(3)

Context: The cat sat on the

Figure 2: Illustration of exponential races for speculative decoding. Each bar represents a potential next token, with height corresponding to arrival time. The first arrival under the draft model distribution Q (left) predicts the first arrival under the target model distribution P (right).

For the rest of the section, we assume the target and draft model distributions, P and Q, be m-th order Markov sources. Then, the acceptance probability $R(\mathbf{j} \mid x_{:n})$ is an m-th order Markov chain, since P and Q are as well. The expected number of accepted tokens is the sum of acceptance probabilities for each vertex in the drafting tree. Therefore, the optimal drafting tree τ^* with k+1 vertices (for speculating k tokens) is the solution to:

$$\tau^* = \underset{\text{tree } \tau, |\tau| = k+1}{\operatorname{arg \, max}} \sum_{\mathbf{i} \in \tau} R(\mathbf{j} \mid x_{:n}). \tag{4}$$

Crucially, for any vertex \mathbf{j} and its descendant \mathbf{j}' in a drafting tree, the acceptance probability is decreasing: $R(\mathbf{j} \mid x_{:n}) \geq R(\mathbf{j}' \mid x_{:n})$. This is because \mathbf{j}' can only be accepted if its ancestor **j** is accepted. Consequently, the top k vertices with the highest acceptance probabilities form a valid tree. Any node j in this top-k list will have all its ancestors \mathbf{j}_{m} (where $m < |\mathbf{j}|$) also present in the list due to their higher acceptance probabilities. This observation leads to a greedy algorithm (Algorithm 3) for constructing an optimal tree with k+1 vertices. Algorithm 3 iteratively builds the tree by greedily adding the next most likely token to be accepted. This is achieved efficiently using a priority queue to maintain candidate vertices, ordered by their acceptance probabilities. The algorithm's computational complexity is $O(k \log k)$ because the loop iterates k times, and each iteration involves priority queue operations (push and pop) with a maximum queue size of 2k, each taking $O(\log k)$ time. Our analysis relies on the acceptance probability function R, which is typically unknown in practice. If we approximate R using an empirical acceptance distribution – effectively treating it as a 0-th order Markov source – the resulting algorithm becomes equivalent to that proposed by Chen et al. (2025).

Algorithm 3 Optimal tree construction

```
1: Input: # drafted tokens k, partial output x_{:n}
                                  ⊳ initialize tree with root only
 2: tree \leftarrow \{()\}
 3: C \leftarrow PRIORITYQUEUE()
 4: ADD(C, (R((0) \mid x_{:n}), (0)))
 5: for all i \in (1, ..., k) do
             _{\mathbf{j}} \leftarrow POPMAX(C)
 6:
             tree \leftarrow tree \cup \{\mathbf{j}\}\
 7:
 8:
             \mathbf{j}_{child} \leftarrow \mathbf{j}||(0)|
            C.Add((R(\mathbf{j}_{child} \mid x_{:n}), \mathbf{j}_{child}))
 9:
             if \mathbf{j}_{|\mathbf{i}|} < |\Omega| then
10:
                   \mathbf{j}_{sibling} \leftarrow \mathbf{j}_{:(|\mathbf{j}|-1)}||(\mathbf{j}_{|\mathbf{j}|}+1)
C.\text{ADD}((R(\mathbf{j}_{sibling} \mid x_{:n}), \mathbf{j}_{sibling}))
11:
12:
13:
             end if
14: end for
15: Return tree
```

We employ this empirical approximation in our experiments. However, as Section 5 will demonstrate, this 0-th order approximation proves to be inaccurate, leading to an underestimation of the speed-up we can achieve with speculative decoding. Developing more refined approximations of R presents a promising avenue for future investigation. In another connection to information theory, the process of generating optimal drafting trees (Algorithm 3) closely resembles the construction of Tunstall codes (Tunstall, 1968). Due to their similarity, quantities in speculative decoding, such as the number of drafted tokens, speed-up, and entropy of the acceptance distribution, have direct counterparts in Tunstall codes: the number of expanded nodes in the Tunstall tree, the expected length of the consumed source symbols, and the source entropy, respectively. This connection allows us to express the expected speed-up of speculative decoding (both GSD and ERSD) in terms

of these quantities. Tunstall codes are a type of variable-to-fixed length source codes used in data compression for discrete sources. In source coding, the goal is to represent sequences of symbols from a source alphabet (like tokens in our case) using the fewest number of bits (in the case of a binary alphabet). Variable-to-fixed length codes, such as Tunstall codes, achieve this by mapping variablelength sequences of source symbols to fixed-length codewords from a code alphabet. Specifically, a Tunstall code takes a variable-length prefix of the source symbol sequence and encodes it into a fixedlength output sequence. This encoding step is repeated until the entire source sequence is processed. Tunstall codes are known to be optimal in the sense that for sufficiently long codewords, the average number of output alphabet symbols per source symbol approaches the entropy of the source – this also holds true for sources with memory (Savari and Gallager, 1997). Let the entropy of the acceptance probability distribution be defined as:

$$\mathbf{H}\left[R\right] = \sum_{x:n \sim P} \mathbf{H}\left[R(\cdot \mid x:n)\right] \tag{5}$$

Theorem 4.1. (Upper bound Tunstall) For speculative decoding employing the optimal drafting strategy τ^* , the expected number of generated tokens is bounded as follows:

$$\mathbf{E}[\# generated \ tokens] \leq \frac{\log |\Omega| + \log(k+1)}{\mathbf{H}[R]}.$$

Details of Theorem 4.1 are provided in Appendix C. As the theorem suggests, for a large number of drafted tokens k, the generation speed-up is fundamentally governed by the entropy of the acceptance distribution, $\mathbf{H}[R]$. Channel simulation algorithms, such as greedy rejection sampling and Poisson functional representation, are explicitly designed to minimize this entropy. Consequently, these methods, which underpin both GSD and ERSD, inherently aim to maximize generation speed-up by reducing $\mathbf{H}[R]$. From a channel simulation perspective, the KL divergence $\mathbf{D}_{\mathrm{KL}}[P||Q]$ between the target distribution P and the draft distribution Q provides a lower bound on this crucial entropy (Li, 2024):

$$\mathbf{D}_{\mathrm{KL}}[P\|Q] \le \mathbf{H}[R]. \tag{6}$$

Furthermore, channel simulation theory provides upper bounds on $\mathbf{H}[R]$ in terms of $\mathbf{D}_{\mathrm{KL}}[P\|Q]$ for greedy rejection coding (Harsha et al., 2010)

(relevant to GSD):

$$\mathbf{H}[R] \le \mathbf{D}_{\mathrm{KL}}[P||Q] + \tag{7}$$
$$(1+\epsilon)\log(\mathbf{D}_{\mathrm{KL}}[P||Q] + 1) + O(1),$$

for any $\epsilon > 0$, and for Poisson functional representation (Li and El Gamal, 2018) (relevant to ERSD):

$$\mathbf{H}[R] \le \mathbf{D}_{KL}[P||Q] + \log(\mathbf{D}_{KL}[P||Q] + 1) + 4.$$
 (8)

These bounds show the connection of speedup in speculative decoding to KL divergence $\mathbf{D}_{\mathrm{KL}}[P||Q]$ between the models. While asymptotically accurate for large k, the bound from Theorem 4.1 is dominated by the full token alphabet size $|\Omega|$ when the number of drafted tokens k is small. For such values of k, we observe that the optimal drafting tree typically explores only a limited number of drafting positions. Indeed, multiple acceptance distributions can yield identical optimal drafting trees and the same acceptance probabilities for all nodes within those trees. Thus, evaluating the bound from Theorem 4.1 for any such distribution provides a valid upper bound for all of them. To simplify the notation and exposition, we focus on the 0-th order acceptance distribution R, noting that our findings can be generalized to higher-order Markov sources. For a given number of drafted tokens k, let d be the maximum index explored in the optimal drafting tree τ_k^* with k+1 vertices, i.e., $d = \max_{\mathbf{j} \in \tau_k^*} \max_i \{i \mid i \in \mathbf{j}\}.$ We define an equivalent acceptance distribution \hat{R} such that for indices $i \leq d$, $\hat{R}(i) = R(i)$, and for i > d, $\hat{R}(i) \le \min_{i' < d} R(i')$. In short, Rmatches R on tree nodes for the first d indices and is upper-bounded by $\min_{i' < d} R(i')$ thereafter. Our objective is to minimize the upper bound on the expected number of accepted tokens. Upon inspection of Theorem 4.1, we see that a tighter bound is achieved by maximizing the entropy of \ddot{R} and minimizing the alphabet size. Minimizing the bound requires strategically distributing the remaining probability mass, $p_{res}=1-\sum_{i=1}^d R(i)$, associated with indices beyond d. For any choice to incorporate m additional indices, entropy maximization is achieved by distributing the residual mass equally across them.

Lemma 4.2. (Upper bound m) For a fixed number of drafted tokens k and initial index range d, consider a 0-th order acceptance probability distribution R. Let $p_{res} = 1 - \sum_{i=1}^{d} R(i)$ be the

Figure 3: Expected number of accepted tokens as a function of the number of drafted tokens for sequence , batch , τ^* tree (optimal), and SpecInfer tree drafting strategies, for GSD and ERSD. Results shown for draft model Q Llama-3.2-1B, and target model P Llama-3.1-70B-Instruct.

residual probability mass. Define R^{res} such that $R^{res}(i) = R(i)$ for $i \le d$, and $R^{res}(d+1) = p_{res}$. Then, for any integer $m \ge \frac{p_{res}}{\min_{i \le d} R(i)}$, the expected number of generated tokens is upper-bounded by:

$$\mathbf{E}\left[\# \ generated \ tokens
ight] \leq rac{\log(d+m) + \log(k+1)}{\mathbf{H}\left[R^{res}\right] + p_{res}\log m}$$

Note: R^{res} defined in above lemma is not \hat{R} .

5 Experiments

To validate our theoretical analysis, we conducted numerical experiments comparing GSD and ERSD across different drafting strategies. We performed open-ended text generation up to 200 tokens, accumulating 100k generated tokens per strategy. The experiments were performed on 8 Nvidia RTX A6000 GPUs, with experiments running for 140 hours of wall-clock time. We estimated the acceptance probability function R using empirical acceptance probabilities for different indices (from sequence and batch), approximating it as a 0th order Markov chain. Based on this estimated R, we computed the optimal drafting tree τ^* for both GSD and ERSD using Algorithm 3. Figure 3 illustrates the expected number of accepted tokens as a function of drafted tokens for the target model Llama-3.1 70B and the draft model Llama-3.2 1B (Grattafiori et al., 2024), used under the

Meta Llama 3.1 and 3.2 Licenses. Figure 4 shows the marginal change in acceptance probability with each additional drafted token. We compare four drafting strategies: batch, sequence, optimal tree (τ^*) , and the SpecInfer tree (Miao et al., 2024), which drafts 3-sequences with the first two drafted tokens being common. For each strategy and speculative decoding method (GSD, ERSD), we present both theoretical and empirical performance. The theoretical plots show the expected number of generated tokens based on the estimated R, while the empirical plots display the actual value observed in our experiments. Figure 3 reveals that for batch drafting with k = 1, GSD outperforms ERSD, consistent with Lemma 3.1. However, with k=2, both methods exhibit comparable performance. For $k \geq 3$, ERSD achieves a higher expected number of accepted tokens. Both methods plateau just below 2, as anticipated. The acceptance probabilities for each index $((0), (1), (2), \dots)$ are shown in Figure 4. For *sequence* drafting, GSD demonstrates superior performance compared to ERSD, owing to sequence 's focus on the first arrivals. Intriguingly, our empirical results also challenge the 0-th order acceptance assumption (Chen et al., 2025). The empirical performance plateaus at a higher level than predicted by the measured R, indicating higherorder Markov dependencies. This can be explained

Figure 4: Marginal probability of acceptance as a function of the number of drafted tokens for sequence, batch, τ^* tree (optimal) drafting strategies, for GSD and ERSD. Results shown for draft model Q Llama-3.2-1B, and target model P Llama-3.1-70B-Instruct.

by regions of language where the target model Pand draft model Q exhibit greater alignment, leading to extended sequences of accepted tokens. The SpecInfer tree achieves slightly improved performance over sequence drafting but still plateaus. As predicted, the optimal τ^* tree strategy yields the best performance for both GSD and ERSD, exhibiting a logarithmic relationship between drafted tokens k and expected generated tokens (Figure 3). At low k, the optimal tree τ^* and sequence strategies show similar performance, with GSD slightly outperforming ERSD. However, as k increases, the performance gap diminishes, and they converge. Figure 3 presents the minimal upper bound derived from Lemma 4.2 by optimizing the parameter mfor each number of drafted tokens k. We also depict the upper bound from Lemma 4.2, calculated with a fixed m for k = 384 to show the behavior of the bound. While the marginal changes in the minimal upper bound are omitted for visual claritydue to their step-like transitions—, we observe that the marginal changes of the fixed-m upper bound closely follow the trends of the optimal τ^* tree .

6 Limitations

Speculative decoding's speed gains are most significant when drafting only a few tokens, k. Therefore, for small values k, GSD is often the most practical

choice. While token-by-token generation was the focus of this work, joint sequence generation in speculative decoding or channel simulation could lead to further improvements, but its computational practicality is uncertain. Furthermore, our current stateless approximation of the acceptance probability function R oversimplifies the contextual nature of language. Developing more context-aware approximations could yield improvements in future work.

7 Conclusion

This work establishes a connection between speculative decoding – a technique for accelerating autoregressive LLM generation – and channel simulation. This connection enabled us to propose ERSD, a novel speculative decoding method. By linking the optimal drafting strategy to Tunstall codes, we derived a theoretical upper bound and the asymptotic relationship between the number of speculated tokens and the expected speed-up, for GSD and ERSD. These findings offer a deeper understanding of, and potential improvements to, the efficiency of speculative decoding.

39: y \leftarrow y \cup \{token\}
40: return y
```

The draft token selection step-sampling without replacement—in the general GSD Algorithm 4 can be implemented using exponential races just as in Algorithm 5, or equivalently the Gumbel-max trick. Furthermore, the verification step in ERSD Algorithm 5 is a significantly simpler compared to GSD.

Algorithm 5 Exponential Race Speculative Decoding

```
1: Input: partial output x_{:n}, draft model Q, target model P, # draft tokens k, draft strategy \tau
  2: for all j \in \tau do
                                                                                                        ▶ Assumes lexicographical ordering of indexes j

19:
20.
              end if
21: end while
22: return y
```

B Speculative decoding via exponential races

We begin by recalling the Poisson matching lemma (Li and Anantharam, 2021), adapted to our notation for discrete alphabets:

Lemma B.1. (Poisson matching lemma) Let P and Q be two probability distributions over the alphabet Ω . Let $E_i \sim Exp(1)$ for each symbol $i \in \Omega$ be independent exponential random variables. Define $I_P^* = \arg\min_{i \in \Omega} \frac{E_i}{p_i}$ and $I_Q^* = \arg\min_{i \in \Omega} \frac{E_i}{q_i}$. The probability that I_P^* is different than I_Q^* , given I_Q^* , is bounded by:

$$\Pr\left\{I_P^* \neq I_Q^* \mid I_Q^*\right\} \le 1 - \left(1 + \frac{q_{I_Q^*}}{p_{I_Q^*}}\right)^{-1}.$$
 (9)

In essence, this lemma bounds the probability that two races, driven by the same underlying exponential random variables but with different distributions P and Q, will have different winners.

Proof. (Lemma 3.1) To obtain the average probability of differing first arrivals, we marginalize the Poisson matching lemma over all possible values of I_Q^* . Let $P_{accept}^{(1)}$ be the probability that the first drafted token in ERSD is accepted. This occurs when the winner of the race under P is the same as the winner under Q,

i.e., $I_P^* = I_Q^*$. Thus:

$$P_{accept}^{(1)} = \mathbf{Pr} \left\{ I_P^* = I_Q^* \right\} \tag{10}$$

$$=1-\mathbf{Pr}\left\{I_{P}^{*}\neq I_{Q}^{*}\right\} \tag{11}$$

$$=1-\mathbf{E}_{I_{O}^{*}}\left[\mathbf{Pr}\left\{I_{P}^{*}\neq I_{Q}^{*}|I_{Q}^{*}\right\}\right]$$
(12)

$$\geq 1 - \mathbf{E}_{I_Q^*} \left[1 - \left(1 + \frac{q_{I_Q^*}}{p_{I_Q^*}} \right)^{-1} \right]$$
 (by Lemma B.1) (13)

$$= \mathbf{E}_{I_Q^*} \left[\left(1 + \frac{q_{I_Q^*}}{p_{I_Q^*}} \right)^{-1} \right] \tag{14}$$

$$= \sum_{i \in \Omega} q_i \frac{1}{1 + \frac{q_i}{p_i}} \quad \text{(since } I_Q^* \sim Q) \tag{15}$$

$$=\sum_{i\in\Omega}\frac{p_iq_i}{p_i+q_i}\tag{16}$$

$$=D_{HM}[P,Q], (17)$$

where the last step follows from the definition of the harmonic mean distance $D_{HM}[P,Q]$. Furthermore, it is known that $P_{accept}^{(1)}$ is upper-bounded by $1 - D_{TV}[P,Q]$ (cite), and in general those bounds do not coincide as:

$$1 - D_{TV}[P, Q] = 1 - \frac{1}{2} \sum_{i \in \Omega} |p_i - q_i|$$
(18)

$$= \frac{1}{2} \sum_{i \in \Omega} p_i + \frac{1}{2} \sum_{i \in \Omega} q_i - \frac{1}{2} \sum_{i \in \Omega} |p_i - q_i|$$
 (19)

$$= \frac{1}{2} \sum_{i \in \Omega} \frac{(p_i + q_i)^2 - |p_i - q_i|(p_i + q_i)}{p_i + q_i}$$
 (20)

$$= \frac{1}{2} \sum_{i \in \Omega} \frac{p_i^2 + 2p_i q_i + q_i^2 - |p_i^2 - q_i^2|}{p_i + q_i}$$
 (21)

$$\geq \frac{1}{2} \sum_{i \in \Omega} \frac{p_i^2 + 2p_i q_i + q_i^2 - (p_i^2 + q_i^2)}{p_i + q_i} \quad \text{(since } |x| \geq x)$$
 (22)

$$=\sum_{i\in\Omega}\frac{p_iq_i}{p_i+q_i}\tag{23}$$

$$=D_{HM}[P,Q]. (24)$$

C Tunstall Codes

This section provides a concise overview of Tunstall coding. Source coding is a fundamental technique for representing sequences of source symbols, like text or tokens, as sequences of bits (or symbols from another alphabet). The goal is efficient representation for storage or transmission. Tunstall coding is a variable-to-fixed length source coding method. This means it parses the source symbol sequence into variable-length subsequences, and then maps each of these subsequences to a fixed-length codeword. Let G denote the expected length of the encoded source subsequence, i.e., $G = \mathbf{E}$ [length of encoded source subsequence]. Tunstall codes are constructed using trees. The construction process begins with a root node. Assuming a source alphabet Ω , the root is expanded to have $|\Omega|$ children. Subsequently, in each step, the leaf node representing the most probable source sequence is expanded by adding $|\Omega|$ children to it. This expansion process is repeated until a desired number of codewords is reached. The structure and construction of this

Tunstall tree, specifically its inner nodes, are identical to the optimal draft tree employed in speculative decoding as described in Algorithm 3; conversly, the leafs of the Tunstall tree correspond to sampling of an additinal token once no more drafted tokens are considered. If the construction process expands k nodes, the resulting Tunstall tree will have $|\Omega| + k(|\Omega| - 1)$ leaves. Each path from the root to a leaf represents a variable-length sequence of source symbols. By assigning a unique codeword of fixed length $\lceil \log{(k(|\Omega| - 1) + |\Omega|)} \rceil$ bits to each leaf node, we create the Tunstall code. Considering the fundamental limit of compression given by the source entropy, we can establish an inequality for compressing a source sequence of length L with a Tunstall code:

$$L\mathbf{H}[R] \le \frac{L}{G}\log\left(k(|\Omega| - 1) + |\Omega|\right) \tag{25}$$

Here, the LHS represents the theoretical minimum number of bits to encode a sequence of length L, and the RHS represents the expected number of bits used by the Tunstall code. The term $\frac{L}{G}$ represents the expected number of codewords needed to encode a source sequence of length L, and $\log\left(k(|\Omega|-1)+|\Omega|\right)$ is the fixed length of each codeword. Due to the connection between Tunstall code construction and Algorithm 3, specifically the optimal drafting tree, the 'length of encoded source sequence' equals 'number of generated tokens' in speculative decoding. Rearranging the equation, we obtain:

$$\mathbf{E} \left[\text{# of generated tokens} \right] \le \frac{\log \left(k(|\Omega| - 1) + |\Omega| \right)}{\mathbf{H} \left[R \right]} \le \frac{\log |\Omega| + \log(k + 1)}{\mathbf{H} \left[R \right]}. \tag{26}$$

Tunstall codes are known to be asymptotically optimal, even for sources with memory (Savari and Gallager, 1997), when a different code for each state is used. This asymptotic optimality means that the gap to the theoretical compression limit becomes constant as k increases. Therefore, this upper bound also characterizes the asymptotic behavior of speculative decoding.
