Abstract—To the best of our knowledge, all existing methods that can generate synthetic brain magnetic resonance imaging (MRI) scans for a specific individual require detailed structural or volumetric information about the individual’s brain. However, such brain information is often scarce, expensive, and difficult to obtain. In this paper, we propose the first approach capable of generating synthetic brain MRI segmentations—specifically, 3D white matter (WM), gray matter (GM), and cerebrospinal fluid (CSF) segmentations—for individuals using their easily obtainable and often readily available demographic, interview, and cognitive test information. Our approach features a novel deep generative model, CSegSynth, which outperforms existing prominent generative models, including conditional variational autoencoder (C-VAE), conditional generative adversarial network (C-GAN), and conditional latent diffusion model (C-LDM). We demonstrate the high quality of our synthetic segmentations through extensive evaluations. Also, in assessing the effectiveness of the individual-specific generation, we achieve superior volume prediction, with Pearson correlation coefficients reaching 0.80, 0.82, and 0.70 between the ground-truth WM, GM, and CSF volumes of test individuals and those volumes predicted based on generated individual-specific segmentations, respectively.

I Introduction

In recent years, the structures and volumes of white matter (WM), gray matter (GM), and cerebrospinal fluid (CSF) in the human brain have garnered significant attention in neuroscience and cognitive science research [11], [20], [42]. These three regions are primarily assessed and quantified through the segmentation of brain magnetic resonance imaging (MRI) scans [50]. However, due to high costs [18] and privacy concerns [46] associated with acquiring brain MRI scans, the WM, GM, and CSF segmentations are substantially underrepresented in research datasets, leading to a data scarcity issue that hinders many important studies. Based on machine learning and generative AI techniques, recent efforts for addressing this issue can be broadly categorized into two main types: First, unconditional data augmentation methods [23], [25], [40] generate synthetic MRI scans that resemble real scans from their training data but do not correspond to any specific individuals. Second, conditional individual-specific

methods [47], [9], [30] aim to generate MRI scans for real-world individuals using detailed structural or volumetric information of the individuals’ brain. However, such required brain information, including precise regional volumes and even neuroimaging scans in other modalities, is often scarce and difficult to obtain.

In this paper, we propose the first approach capable of conditionally generating synthetic individual-specific 3D brain MRI segmentations based on individuals’ easily obtainable and often readily available features that are potentially relevant to their brain structures. As depicted in Fig. 1 (a), the features include demographic information (e.g., age and sex), home interview data (e.g., family and social activities), and cognitive test results (e.g., memory test and reaction time test scores). We aim to develop a deep generative model that can take these features as input and correspondingly generate synthetic 3D WM, GM, and CSF segmentations for the considered individual. Moreover, the model is expected to make reasonable predictions when the input features are modified (e.g., when adjusting age or alcohol consumption data for aging- or alcohol-related studies). *To the best of our knowledge, no existing research addresses these needs, leaving a significant gap in the research field.*

An overview of our approach is outlined in Fig. 1 (b), where we train deep generative models, including the proposed **Conditional Segmentation Synthesis** model—**CSegSynth**, through two steps: *unconditional pre-training* and *conditional fine-tuning*. In *unconditional pre-training*, we utilize a relatively large collection of publicly available MRI scans, i.e., AOMIC ID 1000 [38], to train four unconditional generative models: a variational autoencoder (VAE) [22], a generative adversarial network (GAN) [13], a latent diffusion model (LDM) [32], and an alpha-generative adversarial network (α -GAN) [34]. VAE, GAN, and LDM represent three prominent paradigms of generative modeling: variational inference-based, adversarial learning-based, and denoising diffusion-based [2], respectively. α -GAN can be considered as a combination of VAE and GAN, exhibiting strong performance in uncon-

Fig. 1: (a) An overview of how our proposed deep generative model conditionally generates individual-specific MRI segmentations. Given an individual with easily obtainable features (original or hypothetically modified for studies with control variables), we aim to develop a deep generative model that can generate synthetic 3D MRI segmentations specific to this individual. **(b) An overview of the proposed approach for training the deep generative model.** The training includes two steps: unconditional pre-training based on AOMIC ID1000 [38] and conditional fine-tuning based on a subset of CamCAN [37]. The newly proposed CSegSynth model and its corresponding pre-trained α -GAN model are highlighted with stars.

ditional MRI generation [34]. This first step enables these models to learn detailed structures of the human brain. After training, they can transform randomly sampled noise into synthetic 3D WM, GM, and CSF segmentations that appear realistic but do not correspond to specific individuals. Then, in the *conditional fine-tuning* step, we adapt the four models into four corresponding conditional variants: conditional VAE (C-VAE) [39], conditional GAN (C-GAN) [29], conditional LDM (C-LDM) [32], and CSegSynth. C-VAE, C-GAN, and C-LDM are implemented following their general frameworks. CSegSynth has a novel architecture with neural network-based conditioning modules and additional loss terms that we propose based on α -GAN (elaborated in Section IV). Before fine-tuning, the four conditional models inherit most pre-trained parameters of their unconditional variants, as indicated by the dotted arrows labeled “parameter sharing” in Fig. 1 (b). Furthermore, we utilize a subset of CamCAN [37] and split it into training, validation, and test sets for model training and evaluations (elaborated in Section II-A).

Our *main findings* in this paper are as follows:

1) The proposed CSegSynth model can generate synthetic 3D brain MRI segmentations with state-of-the-art quality, as demonstrated through qualitative and quantitative evaluations

assessing visual appearance, real-versus-synthetic data distribution alignment, image inception distance, and data diversity, in comparison with prominent baseline models, i.e., C-VAE, C-GAN, and C-LDM. (Reported in Section II-B)

2) Based on our proposed training approach in Fig. 1 (b), the generation process of C-VAE, C-GAN, and CSegSynth can be effectively conditioned on the input individual features, as demonstrated by evaluations focusing on the accuracy of predicted total WM, GM, and CSF volumes in generated individual-specific segmentations. In the evaluations, CSegSynth substantially outperforms other deep generative models and several widely-used conventional regression methods that predict these volumes directly based on individual features, including linear regression (LR), polynomial regression (PR), support vector regression (SVR), and feedforward neural network (FFN). Notably, CSegSynth achieved mean absolute percentage errors of 6.82%, 5.03%, and 12.32%, along with statistically significant Pearson correlation coefficients of 0.80, 0.82, and 0.70 for total WM, GM, and CSF volumes, respectively. (Reported in Section II-C)

3) By computing gradients of generated segmentations with respect to input features, CSegSynth can serve as a convenient testbed for quantifying the impact of input features on human

Fig. 2: A comparison of real example segmentations and synthetic segmentations generated by our trained conditional models—C-VAE, C-GAN, C-LDM, and CSegSynth. We present center-cut 2D slices in the sagittal, axial, and coronal views for each 3D segmentation. Please note that, due to CamCAN’s data restrictions, the real examples are sourced from a different public dataset (AOMIC) and are included solely to illustrate the general image quality of real segmentations.

brain structures, offering great potential in neuroscience and cognitive science studies. Moreover, we probed CSegSynth with a set of hypothetically modified input features with increasing ages in two scenarios: “ideal” where other features remain unchanged, and “regressed” where other features are adjusted according to age-based regression. CSegSynth generated plausible hypothetical segmentations in both scenarios. Although we cannot verify the predictions due to the absence of corresponding real brain scans, these observations, along with CSegSynth’s performance in all the above evaluations, suggest its promising potential in future studies that focus on human brain structure prediction. (Discussed in Section III)

II Results

II-A Experimental Setup

Datasets. As shown in Fig. 1 (b), we used AOMIC ID1000 [38] and a subset of CamCAN CC700 [37] for the unconditional pre-training and conditional fine-tuning of deep generative models, respectively. AOMIC ID1000 includes T1-weighted brain MRI scans of 928 healthy young individuals (19 to 26 years old, male/female ratio 0.9), providing the unconditional models with fundamental knowledge of human brain structures. The CamCAN subset includes T1-weighted brain MRI scans of 462 individuals in a wider age range (18 to 87 years old, male/female ratio 1.0), enabling our conditional models to generalize across different ages. Also, for the conditional models, we used 198 features from CamCAN for each individual, including basic demographic information (e.g., age, sex, height, and weight), VSTM colour test results [49],

fluid intelligence test results [5], sentence comprehension test results [31], proverb comprehension test results [17], smoking and drinking habits, as well as employment, marriage, and social activity information collected from interviews [37].¹

Data Preprocessing. For the original MRI scans from both AOMIC and CamCAN, we used the Brain Extraction Tool (BET)² and FMRIB’s Automated Segmentation Tool (FAST)³ for skull stripping and brain segmentation [50], resulting in ground-truth 3D WM, GM, and CSF segmentations of the size $80 \times 128 \times 128$, where each voxel represents the partial volume estimate of WM, GM, or CSF with a cubic size of 8 mm^3 . The CamCAN subset was randomly split into a training set (80%, 370 individuals, male/female ratio 1.1), a validation set (10%, 46 individuals, male/female ratio 1.3), and a test set (10%, 46 individuals, male/female ratio 0.8). Each individual’s input features are represented as a single vector that is standardized based on the mean and standard deviation of the feature values in the training set. The following results are from the test set of CamCAN, which was never disclosed to the trained models.

II-B Quality of Synthetic Segmentations

We report both qualitative and quantitative evaluations of the synthetic segmentations generated by our final conditional models.

Qualitative Evaluation. Following existing work [7], [30], [23], we randomly select one individual from the CamCAN

¹CamCAN features are available in the data application portal <https://camcan-archive.mrc-cbu.cam.ac.uk/dataaccess/datarequest.php>.

test set and present synthetic segmentations that our trained conditional models generated for this individual in Fig. 2. We present center-cut 2D slices in the sagittal, axial, and coronal views for clarity. Since CamCAN is not a public dataset, we cannot show the individual’s real segmentations for direct comparison. Nevertheless, as our goal in this evaluation is to assess the overall image quality, we include visually similar real example segmentations from the publicly available AOMIC dataset in Fig. 2 for reference. We summarize our main findings in the following. Notably, these findings are not specific to the presented individual but generalize across the entire test set.

- C-VAE is only able to capture the overall shape of WM, GM, and CSF. Its synthetic segmentations appear substantially blurrier than those of the other models. This is an inherent limitation of C-VAE and has been also widely observed in other image generation tasks [19].
- The blurriness issue of C-VAE can often be mitigated by replacing the voxel-wise reconstruction loss with the generator-discriminator mini-max loss of C-GAN. However, the training of C-GAN is challenging and prone to instability [19], particularly in our task, where the training data is significantly limited. Consequently, in Fig. 2, we observe substantial unnatural artifacts in the synthetic segmentations of C-GAN.

- As a state-of-the-art deep generative model, C-LDM generates segmentations with superior fidelity compared to C-VAE and C-GAN. However, we find that C-LDM is prone to distortions and inconsistencies. As observed in the axial view of its generated segmentations, the synthetic left and right cerebral hemispheres appear abnormally asymmetric. Similar substantial distortions are also evident in the sagittal view.
- CSegSynth jointly utilizes the reconstruction loss of C-VAE and the generator-discriminator mini-max loss of C-GAN. It achieves superior fidelity compared to C-VAE and C-GAN. Moreover, compared to C-LDM, CSegSynth exhibits stronger robustness against distortions. Most importantly, CSegSynth demonstrates the strongest ability among all trained models in capturing detailed brain structures, as evidenced by more realistic cerebral ventricles and cortical gyri in the synthetic segmentations.

Quantitative Evaluation. We further quantitatively evaluate the quality of the synthetic segmentations generated for all test individuals considering the Maximum Mean Discrepancy (MMD) [12], 2D and 3D Fréchet Inception Distance (2D/3D-FID) [14], and the absolute difference in Structural Similarity Index Measure ($|\Delta SSIM|$) [45] between real and synthetic segmentations. The results, presented in Table I, lead to the following observations:

TABLE III: The correlation between ground-truth and predicted WM, GM, and CSF volumes. We report the Pearson correlation coefficient (r), Spearman’s rank correlation coefficient (ρ), and Kendall’s rank correlation coefficient (τ) of the regression methods and conditional generative models. The highest correlation coefficients for each region are in bold, whereas the second-highest are underlined. The p -values are also reported under the corresponding coefficients, according to which the coefficients are highlighted with a light-green background for statistical significance ($p \leq 5 \times 10^{-2}$) and a pink background for statistical insignificance ($p > 5 \times 10^{-2}$).

	WM			GM			CSF

CSegSynth	0.80 2×10^{-11}	0.80 2×10^{-11}	0.61 2×10^{-9}	0.82 2×10^{-12}	0.82 3×10^{-12}	0.64 4×10^{-10}	0.70 8×10^{-8}	0.76 1×10^{-9}	0.56 4×10^{-8}

- MMD is a statistical metric that quantifies the discrepancy between two data distributions. We use the MONAI library [4] to compute the MMD between the real and synthetic segmentations of all test individuals. CSegSynth achieves the lowest MMD across all three regions, indicating that its synthetic distribution aligns most closely with the real-world distribution.
- FID measures the distance between real and synthetic segmentations in the feature space of a pre-trained image inception model. We adopt the pre-trained RadImageNet ResNet50 (2D) [28] and MedicalNet ResNet50 (3D) [6] for computing 2D-FID and 3D-FID, respectively. 2D-FID evaluates the 3D segmentations slice by slice. We report the average results of the sagittal, axial, and coronal views. 3D-FID directly evaluates the 3D segmentations as a whole. As reported in Table I, CSegSynth achieves the lowest 2D-FID for WM and GM and the second lowest for CSF. Furthermore, CSegSynth achieves the lowest 3D-FID for GM and CSF and the second-lowest for WM. These results demonstrate that, compared to other baselines, CSegSynth’s synthetic segmentations are generally the most similar to the real ones from the perspective of pre-trained inception models. Nevertheless, please note that the two inception models are not particularly pre-trained with brain MRI segmentations. Therefore, their computed FID metrics may diverge from our

visual assessment. For example, the WM segmentations of CSegSynth are visibly superior to those of C-GAN, which is contrary to the 3D-FID results.

- SSIM is a perceptual metric commonly used to assess the similarity between a pair of images. Following recent works [7], [30], we use it to quantify the respective diversity of real and synthetic brain segmentations. Specifically, we randomly sample 500 pairs of real segmentations and compute the mean SSIM between them as a measure of the real-world data diversity, i.e., $SSIM_{real}$. Then, we apply the same procedure to a model’s synthetic segmentations to measure the diversity of this model’s output, i.e., $SSIM_{model}$. The absolute difference $|\Delta SSIM| = |SSIM_{real} - SSIM_{model}|$ quantifies the gap between the synthetic data’s diversity and the real-world diversity. CSegSynth achieves the lowest $|\Delta SSIM|$ by a clear margin, indicating its superior performance in generating segmentations with realistic diversity.

II-C Effectiveness of the Individual-Specific Generation

In this section, we evaluate the accuracy of predicted total WM, GM, and CSF volumes in the synthetic segmentations generated for test individuals, serving as a global indicator of the effectiveness of our individual-specific generation. Specifically, recall that each voxel in the MRI segmentations

TABLE IV: The top-5 most salient features for WM, GM, and CSF volumes, as identified by the trained CSegSynth model. The features are sorted according to the absolute value of their computed gradient. Details of the VSTM (Visual Short-Term Memory) colour test [49] can be found in the CamCAN paper [41] and data portal (<https://camcan-archive.mrc-cbu.cam.ac.uk/dataaccess/datarequest.php>).

WM Volume		GM Volume		CSF Volume	
Feature	Gradient	Feature	Gradient	Feature	Gradient
Sex (Male:0, Female:1)	-1134.64	Sex (Male:0, Female:1)	-978.44	Sex (Male:0, Female:1)	-233.00
Height	867.03	Height	777.48	Weight	171.29
Weight	492.05	Age	-481.22	Age	155.33
Alcohol Consumption	387.00	Employment (No:0, Yes:1)	371.31	Retired (No:0, Yes:1)	138.58
Weekly Working Hours	329.46	Weight	345.15	VSTM colour Precision (set size 1)	-136.88

represents the partial volume estimate of WM, GM, or CSF with a cubic volume of 8 mm^3 . Hence, the ground-truth and predicted volumes for each test individual can be computed by multiplying 8 mm^3 with the sum of voxel values in the individual’s ground-truth and synthetic segmentations, respectively. Additionally, we implemented four widely used regression methods as baselines: linear regression (LR), polynomial regression (PR), support vector regression (SVR), and feedforward neural network (FFN). Similar to the generative models, these regression methods take the same feature vectors as input for each test individual. However, instead of generating segmentations, they directly predict total WM, GM, and CSF volumes, forming a conventional prediction task.

In Table II, we present the Mean Absolute Percentage Error (MAPE), Mean Absolute Error (MAE), and Coefficient of Determination (R^2) between the ground-truth and predicted volumes. Furthermore, in Table III, we report the Pearson correlation coefficient (r), Spearman’s rank correlation coefficient (ρ), and Kendall’s rank correlation coefficient (τ) between the ground-truth and predicted volumes. From the two tables, we can observe that CSegSynth achieves the best performance across all three regions in terms of MAPE, MAE, r , ρ , and τ . It also attains the highest R^2 for WM and GM. Additionally, the p -values of CSegSynth with respect to r , ρ , and τ are at least one order of magnitude lower than those of other methods, highlighting the significance of the correlation between the ground truth and its predictions. These results demonstrate that CSegSynth’s generation process is effectively conditioned on the input individual features and reveal a novel application that, to the best of our knowledge, has not been explored in related works: predicting individuals’ WM, GM, and CSF volumes by conditionally generating their MRI segmentations.

Notably, C-VAE and C-GAN are also highly competitive compared to conventional regression methods, especially regarding MAPE, MAE, and R^2 . For example, in predicting GM volumes, C-VAE and C-GAN achieve MAPE values of 7.33% and 6.10%, respectively, along with r of 0.71 and 0.80, outperforming all regression methods. This demonstrates the overall effectiveness of the proposed training approach with unconditional pre-training and conditional fine-tuning. It is worth mentioning that, even with our training approach, C-LDM is still generally ineffective, as evidenced by relatively high errors in Table II and insignificant correlations in Ta-

ble III. This is due to the difficulty of incorporating volume prediction into its training loss, as the model does not perform complete denoising process and, therefore, does not generate specific segmentations during training. This is an inherent limitation of C-LDM rather than a shortcoming of our training approach.

III Discussion

In this section, we discuss two novel applications of CSegSynth and the limitations of this paper with potential directions for future work.

Application-I Quantifying the Impact of Input Features. Recent neuroscience and cognitive science studies [15], [10], [3] have highlighted the significance of quantifying relationships between individual features (e.g., age and cognitive test performance) and human brain structures, including their regional volumes (e.g., WM and GM volumes). However, this task remains highly challenging due to the hidden, non-linear, and multifaceted nature of these relationships. As evidenced by accurate volume predictions in Section II-C, CSegSynth effectively models the complex relationships between the adopted individual features and brain regional volumes, offering a promising application based on its differentiable architecture: When assessing how a particular feature affects the WM, GM, or CSF volume, we can compute the gradient of the volume—derived from synthetic segmentations generated by CSegSynth—with respect to this feature based on the backward pass of the backpropagation algorithm [35]. The gradient value reflects the extent to which the regional volume would change if this feature varied, thereby quantifying the feature’s impact. Based on the CamCAN test set, the top-5 most salient features for WM, GM, and CSF volumes are presented in Table IV. Positive gradients indicate a positive influence, whereas negative gradients indicate a negative influence. Sex, height, and weight emerge as the top three indicators of WM volume, reflecting the influence of body size: males or individuals with greater height and weight generally exhibit larger WM volumes. Notably, for GM and CSF volumes, age exerts a relatively stronger influence: its negative gradient for GM and positive gradient for CSF suggest that individuals typically experience decreasing GM and increasing CSF with advancing age. Working status (e.g., weekly working hours, employment status, and retirement) and alcohol consumption

Fig. 3: Predicted trajectories of future WM and GM volumes for a test individual based on synthetic future brain segmentations generated by CSegSynth. Predicted volumes under the “ideal” and “regressed” scenarios are shown as purple and blue dots, respectively. Additionally, each plot includes a regression line with a 95% confidence interval highlighted in the corresponding color.

also stand out as salient features—potentially due to their respective correlation with age and sex. Additionally, the precision (set size 1) metric in the VSTM colour (Visual Short-Term Memory) test [49] shows a negative association with CSF volume—higher precision scores are associated with lower expected CSF volumes. Please note that verifying and rigorously interpreting the computed gradients would require additional data and is beyond the scope of this paper. Nonetheless, such insights and this procedure could be valuable for brain-related studies, facilitating hypothesis generation and the identification of key features that merit further investigation. While we do not intend to claim definitive findings, we hope to highlight this promising and novel application, which, to the best of our knowledge, has not been explored in existing synthetic MRI generation works. Furthermore, the above procedure can be conducted in two more fine-grained cases: 1) computing gradients for individuals within specific subgroups (e.g., subgroups of different ages and sexes) to analyze how the input features differentially influence different individual groups, and 2) computing gradients after extracting certain substructures in the generated segmentations (e.g., cerebral ventricles and cortical gyri) to analyze how the input features influence certain brain substructures.

Application-II Hypothetical Segmentation Generation. This application of CSegSynth enables the prediction of hypothetical brain segmentations and the creation of a brain digital twin for individuals under controlled developmental conditions [44], [24], such as simulating aging or modeling the effects of working status and daily activities. In the following, we present a use case where we predict future WM and GM volumes for a middle-aged⁴ male test individual from CamCAN. Specifically, we generate this individual’s future feature vectors by increasing the age value under two scenarios: “ideal” and “regressed.” In the “ideal” scenario, all the

other features remain unchanged, i.e., assuming this individual is able to maintain all the other conditions despite aging. In the “regressed” scenario, for each of the other features, we train a 3-degree polynomial regression model based on other male individuals in the CamCAN dataset to predict the regressed future value. We generate future brain segmentations for this individual based on these hypothetical feature vectors. Then, we compute future WM and GM volumes based on the generated segmentations. Trajectories of the future WM and GM volumes are plotted in Fig. 3. We can observe that, if the current conditions (i.e., all other features) can be maintained despite aging, WM and GM volumes are predicted to remain relatively stable over time. In contrast, if the individual’s other features regress with aging, WM and GM volumes are expected to decline substantially and would align closely with the population trend of the CamCAN dataset, which we computed via regression but cannot shown here directly due to data restrictions. Finally, we emphasize that these are only hypothetical observations based on synthetic segmentations. Due to the absence of ground-truth future data for this individual, we cannot validate these predictions. This analysis is intended solely to demonstrate a potential application of CSegSynth, rather than to establish any claims or findings.

This work has several limitations that require future efforts to address: First, although CSegSynth has achieved state-of-the-art performance in the generation of high-quality individual-specific segmentations, a noticeable gap remains between the real and generated segmentations, as shown in Fig. 2. This limitation is primarily due to the relatively small size of the training dataset. We will explore how to further improve the quality of generated segmentations by incorporating additional training data. Second, in Section II-C, the effectiveness of the individual-specific generation is evaluated in terms of overall WM, GM, and CSF volumes. It could be beneficial to conduct a more fine-grained assessment involving specific brain structures. However, as this lies beyond the

⁴We are unable to report the exact age due to data privacy concerns.

scope of this paper (i.e., the development of the generative model rather than the downstream analysis), we consider this as an important direction for future work. Third, in the above two applications, there are extensive observations that align with domain knowledge and intuition. However, due to the lack of ground-truth data, these observations cannot be verified. We are actively seeking such datasets with the goal of conducting more rigorous analyses.

IV Methods

In this section, we introduce the details of our approach, including the adopted deep generative models and some implementation details.

IV-A Notation Definition

We first define the notations that are necessary for the discussion. After the brain extraction and segmentation introduced in Section II-A, the AOMIC dataset [38] for model pre-training is denoted as $\{(\mathbf{x}_{wm}^i, \mathbf{x}_{gm}^i, \mathbf{x}_{csf}^i)\}$, where $\mathbf{x}_{wm}^i$, $\mathbf{x}_{gm}^i$, and $\mathbf{x}_{csf}^i$ are the WM, GM, and CSF segmentations of the i -th individual in the dataset. Each segmentation is a 3-dimensional tensor of the size $80 \times 128 \times 128$, i.e., $\mathbf{x}_{wm}^i, \mathbf{x}_{gm}^i, \mathbf{x}_{csf}^i \in [0, 1]^{80 \times 128 \times 128}$, where each value in the tensor denotes the partial volume of WM, GM, or CSF within its corresponding cubic and, therefore, is between 0 and 1. For the convenience of computing, regarding each individual, we stack the three segmentations together with the background to obtain a single 4-dimensional tensor:

$$\mathbf{x}^i = [\mathbf{x}_{wm}^i \parallel \mathbf{x}_{gm}^i \parallel \mathbf{x}_{csf}^i \parallel (1 - \mathbf{x}_{wm}^i - \mathbf{x}_{gm}^i - \mathbf{x}_{csf}^i)], \quad (1)$$

where $[\cdot \parallel \cdot]$ denotes the stack of tensors. In this way, the pre-training dataset can be denoted as $\mathcal{X}_{pre} = \{\mathbf{x}^i\}$, where $\mathbf{x}^i \in [0, 1]^{4 \times 80 \times 128 \times 128}$. Regarding the fine-tuning process, we adopted the CamCAN dataset from the CamCAN repository⁵ [41], [37], which is denoted as $\mathcal{X}_{fin} = \{(\mathbf{x}^i, \mathbf{v}^i, \mathbf{y}^i)\}$, where $\mathbf{x}^i \in [0, 1]^{4 \times 80 \times 128 \times 128}$ also denotes the stacked segmentations and background of the i -th individual in $\mathcal{X}_{fin}$, $\mathbf{v}^i \in \mathbb{R}^4$ is a 4-dimensional vector denoting the ground-truth WM, GM, CSF, and background volumes, and $\mathbf{y}^i$ is a feature vector representing the individual's input features.

IV-B The Pre-Training Process

The pre-training process aims to utilize $\mathcal{X}_{pre} = \{\mathbf{x}^i\}$ to train deep generative models that can generate high-quality MRI segmentations that do not correspond to any specific individuals but appear similar to those real ones in $\mathcal{X}_{pre}$. As introduced above, we adapted four deep generative models: VAE, GAN, LDM, and α -GAN. In the following, we introduce the training of the four models respectively.

IV-B1 Variational Autoencoder (VAE)

An overview of the VAE model [22] is depicted in Fig. 4 (a), where the model consists of an encoder and a decoder. The encoder encodes each input segmentation $\mathbf{x} \in [0, 1]^{4 \times 80 \times 128 \times 128}$ from $\mathcal{X}_{pre}$ into the distribution $q_\phi(\mathbf{z}|\mathbf{x})$, which is assumed to

be an isotropic multivariate Gaussian in a 1024-dimensional hidden space, i.e., $q_\phi(\mathbf{z}|\mathbf{x}) = \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}, \sigma^2 \mathbf{I})$, where $\boldsymbol{\mu}, \sigma^2 \in \mathbb{R}^{1024}$. Then, a vector $\mathbf{z}^{(l)} \in \mathbb{R}^{1024}$ is sampled from $q_\phi(\mathbf{z}|\mathbf{x})$ and decoded by the decoder to obtain the reconstructed segmentation. Specifically, the encoder mainly consists of 3D convolutional neural networks (CNNs), ConvNeXt [26] blocks, layer normalization [1], and feedforward neural networks (FFNs). An overview of the encoder structure is presented in Fig. 5, where the 3D CNNs are labeled with their kernel size (e.g., $3 \times 5 \times 5$) and the input/output channel size (e.g., $4/16$). Also, the ConvNeXt blocks are labeled with the repetition times (i.e., $\times 1$ and $\times 3$). The decoder consists of one 3D transposed CNN, multiple 3D CNNs, ConvNeXt blocks, upsampling layers, and layer normalization. In Fig. 5, the 3D transposed CNN is labeled with the kernel size (i.e., $10 \times 16 \times 16$). Also, the upsampling layers are labeled with the upsampling factor (i.e., $2 \times$).

During training, we split $\mathcal{X}_{pre}$ into a training set (836 individuals) and a validation set (92 individuals). The training loss regarding each input segmentation $\mathbf{x}$ is defined as follows:

$$\mathcal{L}_{vae}(\mathbf{x}; \phi, \theta) = \lambda_1 KL(q_\phi(\mathbf{z}|\mathbf{x}) \parallel \mathcal{N}(\mathbf{z}; \mathbf{0}, \mathbf{I})) - \lambda_2 \frac{1}{L} \sum_{l=1}^L \log p_\theta(\mathbf{x}|\mathbf{z}^{(l)}), \quad (2)$$

where ϕ and θ denote the parameters of the encoder and decoder, respectively. $KL(q_\phi(\mathbf{z}|\mathbf{x}) \parallel \mathcal{N}(\mathbf{z}; \mathbf{0}, \mathbf{I}))$ denotes the Kullback-Leibler (KL) divergence between the encoded distribution and the assumed prior distribution (a standard Gaussian). $\mathbf{z}^{(l)}$ is the l -th sample drawn from $q_\phi(\mathbf{z}|\mathbf{x})$ based on the reparameterization trick [22]. λ_1 and λ_2 are hyperparameters for balancing two loss terms. We employ the AdamW [27] optimization algorithm to optimize ϕ and θ . After training, a new segmentation can be generated by decoding a vector that is randomly sampled from the prior distribution—standard Gaussian.

IV-B2 Generative Adversarial Network (GAN)

We adopt the Wasserstein GAN with gradient penalty [13] in our approach. An overview of the model structure is given in Fig. 4 (c). Specifically, the model consists of a generator G_θ and a discriminator D_ω that compete with each other during training: the discriminator aims to discriminate synthetic segmentations generated by the generator from real segmentations, while the generator aims to improve the quality of its synthetic segmentations to fool the discriminator. The parameters of the generator and the discriminator, i.e., θ and ω , respectively, are optimized in separate steps with different loss functions. The loss function for the discriminator is:

$$\mathcal{L}_{dis}(\mathbf{x}, \hat{\mathbf{x}}, \tilde{\mathbf{x}}; \omega) = D_\omega(\hat{\mathbf{x}}) - D_\omega(\mathbf{x}) + \lambda(\|\nabla_{\tilde{\mathbf{x}}} D_\omega(\tilde{\mathbf{x}})\|_2 - 1)^2, \quad (3)$$

where $\mathbf{x}$ is a sampled real training segmentation. $\hat{\mathbf{x}}$ is a synthetic segmentation generated by the generator based on a noise vector $\hat{\mathbf{z}} \in \mathbb{R}^{1024}$ that is sampled from the prior distribution—a multivariate standard Gaussian $\mathcal{N}(\mathbf{z}; \mathbf{0}, \mathbf{I})$, i.e., $\hat{\mathbf{x}} = G_\theta(\hat{\mathbf{z}})$, $\hat{\mathbf{z}} \sim \mathcal{N}(\mathbf{z}; \mathbf{0}, \mathbf{I})$. $D_\omega(\hat{\mathbf{x}}), D_\omega(\mathbf{x}) \in \mathbb{R}$ are computed

⁵<http://www.mrc-cbu.cam.ac.uk/datasets/camcan/>

Fig. 4: An overview of the model structures of VAE, C-VAE, GAN, C-GAN, LDM, and C-LDM. The triplet margin loss of C-GAN is not shown for clarity. Please refer to Section IV-C2 for details.

by the discriminator for $\hat{x}$ and x , respectively. The term $\lambda(\|\nabla_{\hat{x}} D_{\omega}(\hat{x})\|_2 - 1)^2$ is the gradient penalty [13] that aims to enforce the Lipschitz constraint [13] over D_{ω} , where $\hat{x} = \epsilon x + (1 - \epsilon)\hat{x}$, and ϵ is sampled from a uniform distribution between 0 and 1, i.e., $\epsilon \sim U[0, 1]$. λ is a hyperparameter for balancing loss terms. Then, the loss function for the generator is defined as:

$$\mathcal{L}_{gen}(\hat{z}; \theta) = -D_{\omega}(G_{\theta}(\hat{z})), \quad (4)$$

which aims to optimize θ to improve the discriminator's "score" for the generator's synthetic segmentation $G_{\theta}(\hat{z})$.

In our implementation, the generator and discriminator share the basic structures of the decoder and encoder of the VAE model (cf. Fig. 5), respectively. One major difference is that the output layer of the discriminator is only one FFN block that has real number outputs. The GAN model is trained over $\mathcal{X}_{pre}$ with the Adam optimization algorithm [21]. After training, we can sample noise vectors from the prior noise distribution and use the generator to generate new synthetic segmentations.

IV-B3 Latent Diffusion Model (LDM)

We adopted the MONAI library [4] to implement and train an LDM model [32], which consists of an autoencoder (comprising an encoder and a decoder), a forward diffusion process, and a reverse diffusion (i.e., denoising) process. An overview of the model is presented in Fig. 4 (e). Similar to VAE, the autoencoder represents the original segmentations in a more compact and efficient latent space. The encoder and decoder are trained with a combination of L1 reconstruction loss, perceptual loss [48], adversarial loss [8], and KL regularization, as proposed by Pinaya et al. [30]. In the diffusion process, LDM adds noise to the latent representation of the given segmentation x , i.e., z , step by step and eventually converts it into z_T , which is close to a sample from the standard Gaussian $\mathcal{N}(z; 0, I)$. Here, T denotes the number of steps and is set to 1,000 in our experiment. In the denoising process, given a latent representation sampled from $\mathcal{N}(z; 0, I)$, i.e., $\hat{z}_T$, LDM aims to remove the presumed noise in $\hat{z}_T$ step by step and converts it into $\hat{z}$ that can be decoded into a plau-

Fig. 5: An overview of the encoder structure and the decoder structure of our VAE model.

sible synthetic segmentation $\hat{\mathbf{x}}$. The forward diffusion process only requires sampling the noise to add in each step from a standard Gaussian and does not involve training parameters. The denoising process leverages a UNet module [33] to predict the noise to remove at each step. Its training loss is defined as:

$$\mathcal{L}_{ldm}(\mathbf{z}, \epsilon, t; \theta) = \|\epsilon - \epsilon_{\theta}(\mathbf{z}_t, t)\|_2, \quad (5)$$

where $\mathbf{z}$ is the latent representation of a sampled real training segmentation. ϵ is randomly sampled from a standard Gaussian. t denotes a step number uniformly sampled between 1 and T . θ denotes the UNet module's parameters. $\mathbf{z}_t$ denotes the result of the diffusion process starting with $\mathbf{z}$ after t steps, which can be obtained based on ϵ [16]. $\epsilon_{\theta}(\mathbf{z}_t, t)$ denotes the output of the UNet module given $\mathbf{z}_t$ and t . The module is trained based on the Adam algorithm [21]. After training, it can be readily used to denoise latent representations randomly sampled from $\mathcal{N}(\mathbf{z}; \mathbf{0}, \mathbf{I})$ to generate new segmentations, as elaborated in [16].

IV-B4 Alpha-Generative Adversarial Network (α -GAN)

The α -GAN model [34], [23] consists of an encoder E_{ϕ} , a code discriminator C_{η} , a generator G_{θ} , and a discriminator D_{ω} , as depicted in Fig. 6 (a). The α -GAN model is trained with three loss functions. The loss function for the encoder and generator is:

$$\begin{aligned} \mathcal{L}_{a1}(\mathbf{x}, \hat{\mathbf{z}}_{rnd}; \phi, \theta) = & -D_{\omega}(\hat{\mathbf{x}}_{rnd}) - D_{\omega}(\hat{\mathbf{x}}_{rec}) - \lambda_1 C_{\eta}(\hat{\mathbf{z}}_{rec}) \\ & + \lambda_2 L_{BCE}(\hat{\mathbf{x}}_{rec}, \mathbf{x}), \end{aligned} \quad (6)$$

where $\mathbf{x}$ is a sampled real segmentation. $\hat{\mathbf{z}}_{rnd} \sim \mathcal{N}(\mathbf{z}; \mathbf{0}, \mathbf{I})$ is a random noise sampled from the prior distribution. ϕ and θ de-

note the parameters of the encoder and generator, respectively. $\hat{\mathbf{x}}_{rnd} = G_{\theta}(\hat{\mathbf{z}}_{rnd})$ is a new synthetic segmentation generated by the generator G_{θ} based on $\hat{\mathbf{z}}_{rnd}$. $\hat{\mathbf{z}}_{rec} = E_{\phi}(\mathbf{x})$ is the encoded vector of $\mathbf{x}$. $\hat{\mathbf{x}}_{rec} = G_{\theta}(\hat{\mathbf{z}}_{rec})$ is a reconstruction of $\mathbf{x}$ based on $\hat{\mathbf{z}}_{rec}$. $C_{\eta}(\hat{\mathbf{z}}_{rec})$ denotes the “score” computed by the code discriminator C_{η} regarding $\hat{\mathbf{z}}_{rec}$. $L_{BCE}(\hat{\mathbf{x}}_{rec}, \mathbf{x})$ denotes the voxel-wise binary cross entropy (BCE) loss between the reconstruction $\hat{\mathbf{x}}_{rec}$ and the original segmentation $\mathbf{x}$.

The loss function for training the discriminator D_{ω} is:

$$\begin{aligned} \mathcal{L}_{a2}(\mathbf{x}, \hat{\mathbf{z}}_{rnd}; \omega) = & D_{\omega}(\hat{\mathbf{x}}_{rnd}) + D_{\omega}(\hat{\mathbf{x}}_{rec}) - 2D_{\omega}(\mathbf{x}) \\ & + \lambda_3 \left((\|\nabla_{\tilde{\mathbf{x}}} D_{\omega}(\tilde{\mathbf{x}})\|_2 - 1)^2 + (\|\nabla_{\tilde{\mathbf{x}'}} D_{\omega}(\tilde{\mathbf{x}'})\|_2 - 1)^2 \right), \end{aligned} \quad (7)$$

where $\tilde{\mathbf{x}} = \epsilon\mathbf{x} + (1 - \epsilon)\hat{\mathbf{x}}_{rnd}$, $\tilde{\mathbf{x}'} = \epsilon'\mathbf{x} + (1 - \epsilon')\hat{\mathbf{x}}_{rec}$, and $\epsilon, \epsilon' \sim U[0, 1]$, denoting the gradient penalty [13].

The loss function for training the code discriminator C_{η} is:

$$\begin{aligned} \mathcal{L}_{a3}(\mathbf{x}, \hat{\mathbf{z}}_{rnd}; \eta) = & C_{\eta}(\hat{\mathbf{z}}_{rec}) - C_{\eta}(\hat{\mathbf{z}}_{rnd}) + \lambda_4 (\|\nabla_{\tilde{\mathbf{z}}} C_{\eta}(\tilde{\mathbf{z}})\|_2 - 1)^2, \end{aligned} \quad (8)$$

where $\tilde{\mathbf{z}} = \epsilon''\hat{\mathbf{z}}_{rnd} + (1 - \epsilon'')\hat{\mathbf{z}}_{rec}$, $\epsilon'' \in U[0, 1]$. $\lambda_1, \lambda_2, \lambda_3$, and λ_4 are hyperparameters for balancing loss terms.

The generator and discriminator of α -GAN share the same structures of the generator and discriminator of the GAN model, respectively. The encoder is implemented based on the discriminator of the GAN model by changing the output dimension of the last FFN layer from 1 to 1024. The code discriminator is implemented as an FFN block with three linear layers. We train the α -GAN model with the Adam optimization as well. After training, new synthetic segmentations can be generated by feeding the generator with noise vectors sampled from the prior distribution.

IV-C The Fine-tuning Process

The fine-tuning process aims to train four conditional generative models, i.e., C-VAE, C-GAN, C-LDM, and CSegSynth, using the aforementioned dataset $\mathcal{X}_{fin} = \{(\mathbf{x}^i, \mathbf{v}^i, \mathbf{y}^i)\}$, where $\mathbf{x}^i$, $\mathbf{v}^i$, and $\mathbf{y}^i$ denote stacked segmentations, ground-truth volumes, and input features, respectively.

IV-C1 Conditional Variational Autoencoder (C-VAE)

The general structure of the C-VAE model [39] is depicted in Fig. 4 (b), where the model consists of a conditional encoder, a conditional decoder, and a prior network. Compared with the pre-trained VAE model, cf. Fig. 4 (a), both the encoding of the segmentation $\mathbf{x}$ and the decoding of the sampled vector $\mathbf{z}^{(l)}$ are conditioned on the individual's feature vector $\mathbf{y}$, i.e., $q_{\phi}(\mathbf{z}|\mathbf{x}, \mathbf{y})$ and $p_{\theta}(\mathbf{x}|\mathbf{z}^{(l)}, \mathbf{y})$, respectively. The conditional encoding is achieved by conditioning the input of the two FFN blocks that compute μ and σ^2 in the original VAE encoder (cf. left bottom in Fig. 5) on $\mathbf{y}$. Specifically, denoting the original input of the two FFN blocks as $\mathbf{h}$, we add additional FFN layers, denoted as the function $FFN_e(\cdot)$, to update $\mathbf{h}$ to $\mathbf{h} = \mathbf{h} + FFN_e(\mathbf{y})$. The conditional decoding is achieved by conditioning the sampled vector $\mathbf{z}^{(l)}$ on $\mathbf{y}$ in a similar way: $\mathbf{z}^{(l)} = \mathbf{z}^{(l)} + FFN_d(\mathbf{y})$. The prior network

Fig. 6: An overview of the model structures of α -GAN and CSegSynth. The triplet margin loss of CSegSynth is not shown for clarity. Please refer to Section IV-C4 for details.

aims to estimate a prior distribution that is conditioned on $\mathbf{y}$, i.e., $p_\theta(\mathbf{z}|\mathbf{y})$. We assume the prior distribution to be an isotropic multivariate Gaussian, i.e., $p_\theta(\mathbf{z}|\mathbf{y}) = \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}, \sigma^2 \mathbf{I})$. Accordingly, the prior network is implemented as two FFN blocks that compute $\boldsymbol{\mu}$ and σ^2 based on $\mathbf{y}$: $\boldsymbol{\mu} = \text{FFN}_{p1}(\mathbf{y})$ and $\sigma^2 = \text{FFN}_{p2}(\mathbf{y})$. The loss function regarding each real training segmentation $\mathbf{x}$ with its corresponding feature vector $\mathbf{y}$ and ground-truth volume $\mathbf{v}$ is defined as follows:

$$\begin{aligned} \mathcal{L}_{cvae}(\mathbf{x}, \mathbf{y}, \mathbf{v}; \phi, \theta) = & \lambda_1 KL(q_\phi(\mathbf{z}|\mathbf{x}, \mathbf{y})||p_\theta(\mathbf{z}|\mathbf{y})) - \lambda_2 \frac{1}{L} \sum_{l=1}^L \log p_\theta(\mathbf{x}|\mathbf{z}^{(l)}, \mathbf{y}) \\ & + \lambda_3 LI(\text{Vol}(\hat{\mathbf{x}}), \mathbf{v}), \end{aligned} \quad (9)$$

where ϕ and θ denote the parameters to learn, and $KL(q_\phi(\mathbf{z}|\mathbf{x}, \mathbf{y})||p_\theta(\mathbf{z}|\mathbf{y}))$ denotes the KL divergence between the encoded distribution $q_\phi(\mathbf{z}|\mathbf{x}, \mathbf{y})$ and the estimated prior $p_\theta(\mathbf{z}|\mathbf{y})$. $\hat{\mathbf{x}}$ denotes a reconstruction of $\mathbf{x}$ generated by the decoder based on a random sample from $q_\phi(\mathbf{z}|\mathbf{x}, \mathbf{y})$. $\text{Vol}(\hat{\mathbf{x}})$ denotes the volume vector computed from $\hat{\mathbf{x}}$. Furthermore, $LI(\text{Vol}(\hat{\mathbf{x}}), \mathbf{v})$ denotes the mean absolute error between $\text{Vol}(\hat{\mathbf{x}})$ and $\mathbf{v}$. λ_1, λ_2 , and λ_3 are hyperparameters for balancing loss terms. We used the Adam algorithm for training, after which, given a new individual with the feature vector $\hat{\mathbf{y}}$, we first use the prior network to estimate the conditional prior distribution $p_\theta(\mathbf{z}|\hat{\mathbf{y}})$. Then, we sample a vector from $p_\theta(\mathbf{z}|\hat{\mathbf{y}})$ and use the decoder to generate $\hat{\mathbf{x}}$, i.e., $\hat{\mathbf{x}} = \arg \max_{\mathbf{x}} p_\theta(\mathbf{x}|\hat{\mathbf{z}}, \hat{\mathbf{y}})$, $\hat{\mathbf{z}} \sim p_\theta(\mathbf{z}|\hat{\mathbf{y}})$, where $\hat{\mathbf{x}}$ is conditioned on $\hat{\mathbf{y}}$ and, therefore, specific

to this individual.

IV-C2 Conditional Generative Adversarial Network (C-GAN)

We present an overview of the C-GAN structure in Fig. 4 (d), which is designed for the segmentation generation task of this paper based on the generic conditional generative adversarial nets [29]. Compared with the pre-trained GAN model, cf. Fig. 4 (c), there are mainly two changes: 1) The generator G_θ becomes conditioned on the input feature vector $\mathbf{y}$, i.e., $\hat{\mathbf{x}} = G_\theta(\hat{\mathbf{z}}|\mathbf{y})$, $\hat{\mathbf{z}} \sim \mathcal{N}(\mathbf{z}; \mathbf{0}, \mathbf{I})$. In this way, we can condition the synthetic segmentations on the input features and generate segmentations for specific individuals. 2) We compute the WM, GM, CSF, and background volumes in generated segmentations and use them in the training loss. Specifically, we add the prediction error $LI(\text{Vol}(\hat{\mathbf{x}}), \mathbf{v})$ as an additional term of the generator's training loss, where $\text{Vol}(\hat{\mathbf{x}})$ denotes computed volumes in $\hat{\mathbf{x}}$, and $LI(\text{Vol}(\hat{\mathbf{x}}), \mathbf{v})$ computes the mean absolute error with respect to $\mathbf{v}$. The loss functions for the generator and discriminator are defined as follows:

$$\begin{aligned} \mathcal{L}_{cgen}(\hat{\mathbf{z}}, \mathbf{y}, \mathbf{v}; \theta) = & -D_\omega(\hat{\mathbf{x}}) + \lambda_1 LI(\text{Vol}(\hat{\mathbf{x}}), \mathbf{v}) \\ & + \lambda_2 TML(\mathbf{v}, \text{Vol}(\hat{\mathbf{x}}), \text{Vol}(\hat{\mathbf{x}}')), \end{aligned} \quad (10)$$

$$\mathcal{L}_{cdis}(\mathbf{x}, \mathbf{y}; \omega) = D_\omega(\hat{\mathbf{x}}) - D_\omega(\mathbf{x}) + \lambda_3 (\|\nabla_{\hat{\mathbf{x}}} D_\omega(\hat{\mathbf{x}})\|_2 - 1)^2, \quad (11)$$

where $\hat{\mathbf{z}} \sim \mathcal{N}(\mathbf{z}; \mathbf{0}, \mathbf{I})$, $\hat{\mathbf{x}} = G_\theta(\hat{\mathbf{z}}|\mathbf{y})$, $\tilde{\mathbf{x}} = \epsilon \mathbf{x} + (1 - \epsilon)\hat{\mathbf{x}}$, $\epsilon \sim U[0, 1]$. Please note that $TML(\mathbf{v}, \text{Vol}(\hat{\mathbf{x}}), \text{Vol}(\hat{\mathbf{x}}'))$ denotes a triplet margin loss [36], which uses $\mathbf{v}$ as the ‘‘anchor,’’

$Vol(\hat{\mathbf{x}})$ as the “positive example” that should be close to $\mathbf{v}$, and $Vol(\hat{\mathbf{x}}')$ as the “negative example” that should deviate from $\mathbf{v}$ by a margin compared to $Vol(\hat{\mathbf{x}})$. Here, $\hat{\mathbf{x}}'$ denotes a random synthetic segmentation generated by the generator based on $\hat{\mathbf{z}}$ and $\mathbf{y} + \mathbf{y}_n$, where $\mathbf{y}_n$ has the same size of $\mathbf{y}$ but is sampled from a standard Gaussian. λ_1 , λ_2 and λ_3 are hyperparameters for balancing loss terms.

The discriminator shares the structure of the discriminator of the pre-trained GAN model. In the conditional generator, we add an additional FFN layer, denoted as $FFN_{cgan}(\cdot)$, on top of the original generator of the pre-trained GAN model. The FFN layer conditions the input vector $\hat{\mathbf{z}}$ on $\mathbf{y}$, i.e., $\hat{\mathbf{z}} = \hat{\mathbf{z}} + FFN_{cgan}(\mathbf{y})$. The generator and discriminator are updated in separate steps based on the Adam algorithm. After training, given a new individual with the feature vector $\hat{\mathbf{y}}$, the individual-specific segmentations can be generated as $\hat{\mathbf{x}} = G_\theta(\hat{\mathbf{z}}|\hat{\mathbf{y}})$, $\hat{\mathbf{z}} \sim \mathcal{N}(\mathbf{z}; \mathbf{0}, \mathbf{I})$.

IV-C3 Conditional Latent Diffusion Model (C-LDM)

An overview of the C-LDM model [32] is given in Fig. 4 (f). Compared to LDM, cf. Fig. 4 (e), the denoising process of C-LDM is conditioned on the feature vector $\mathbf{y}$. Specifically, the UNet module in the denoising process of the original LDM is augmented with a cross-attention mechanism [43] that uses a transformation of $\mathbf{y}$ as “keys” and “values” in the cross attention, as elaborated in [32]. Correspondingly, the loss function is updated as:

$$\mathcal{L}_{cldm}(\mathbf{z}, \epsilon, t, \mathbf{y}; \theta) = \|\epsilon - \epsilon_\theta(\mathbf{z}_t, t, \mathbf{y})\|_2, \quad (12)$$

where $\epsilon_\theta(\mathbf{z}_t, t, \mathbf{y})$ denotes the output of the conditional UNet module at step t given the latent representation of the current step, i.e., $\mathbf{z}_t$, and the feature vector $\mathbf{y}$. Other notations are defined the same as Eq. (5). After training, C-LDM is expected to conduct the denoising of a random sample $\hat{\mathbf{z}}_T$ from $\mathcal{N}(\mathbf{z}; \mathbf{0}, \mathbf{I})$ with the condition of a given individual’s feature vector and generate a synthetic segmentation $\hat{\mathbf{x}}$ that is specific to the individual, as depicted in Fig. 4 (f). Please note that the encoder and the decoder keep the original structures in LDM and inherit the pre-trained parameters.

IV-C4 Conditional Segmentation Synthesis model (CSegSynth)

An overview of the proposed CSegSynth model is given in Fig. 6 (b), which consists of an encoder E_ϕ , a code discriminator C_η , a prior network P_ψ , a generator G_θ , and a discriminator D_ω . During training, given a sampled real segmentation $\mathbf{x}$. The encoder E_ϕ first encodes $\mathbf{x}$ into a vector $\hat{\mathbf{z}}_{rec}$, which, on the one hand, is fed to the code discriminator C_η to obtain a code “score” $C_\eta(\hat{\mathbf{z}}_{rec})$, and on the other hand, is fed to the generator G_θ to obtain a reconstruction of $\mathbf{x}$, i.e., $\hat{\mathbf{x}}_{rec}$. Then, we sample a random vector $\hat{\mathbf{z}}_{rnd}$ from a prior distribution $\mathcal{N}(\mathbf{z}; \mathbf{0}, \mathbf{I})$. The prior network P_ψ conditions $\hat{\mathbf{z}}_{rnd}$ on the feature vector $\mathbf{y}$ and computes $\hat{\mathbf{z}}_{cnd}$, which, on the one hand, is also fed to the code discriminator, i.e., $C_\eta(\hat{\mathbf{z}}_{cnd})$, and on the other hand, is fed to the generator, obtaining a new synthetic segmentation $\hat{\mathbf{x}}_{cnd}$ that is conditioned on $\mathbf{y}$. Lastly, the discriminator D_ω computes “scores” for both the reconstruction and the synthetic segmentation: $D_\omega(\hat{\mathbf{x}}_{rec})$ and

$D_\omega(\hat{\mathbf{x}}_{cnd})$. Based on these notations, we propose three training functions that learn the parameters of involved modules in separate steps:

$$\begin{aligned} \mathcal{L}_{c1}(\mathbf{x}, \mathbf{y}, \mathbf{v}, \hat{\mathbf{z}}_{rnd}; \phi, \theta, \psi) = & \\ & - D_\omega(\hat{\mathbf{x}}_{cnd}) - D_\omega(\hat{\mathbf{x}}_{rec}) - \lambda_1 (C_\eta(\hat{\mathbf{z}}_{cnd}) + C_\eta(\hat{\mathbf{z}}_{rec})) \\ & + \lambda_2 (LI(Vol(\hat{\mathbf{x}}_{cnd}), \mathbf{v}) + LI(Vol(\hat{\mathbf{x}}_{rec}), \mathbf{v})) \\ & + \lambda_3 L_{BCE}(\hat{\mathbf{x}}_{rec}, \mathbf{x}) + \lambda_4 TML(\mathbf{v}, Vol(\hat{\mathbf{x}}_{cnd}), Vol(\hat{\mathbf{x}}'_{cnd})), \end{aligned} \quad (13)$$

where ϕ , θ , and ψ denote that this function is for training the encoder, the generator, and the prior network. Minimizing $-D_\omega(\hat{\mathbf{x}}_{cnd}) - D_\omega(\hat{\mathbf{x}}_{rec})$ drives the generator to generate segmentations with higher quality based on outputs of both the prior network and the encoder. The term $-\lambda_1 (C_\eta(\hat{\mathbf{z}}_{cnd}) + C_\eta(\hat{\mathbf{z}}_{rec}))$ improves the prior network and the encoder based on the judgment of the code discriminator. The term $\lambda_2 (LI(Vol(\hat{\mathbf{x}}_{cnd}), \mathbf{v}) + LI(Vol(\hat{\mathbf{x}}_{rec}), \mathbf{v}))$ regularizes the generated segmentations regarding the ground-truth volume $\mathbf{v}$. The term $\lambda_3 L_{BCE}(\hat{\mathbf{x}}_{rec}, \mathbf{x})$ improves the generator based on voxel-wise binary cross entropy loss between $\mathbf{x}$ and the reconstruction $\hat{\mathbf{x}}_{rec}$. $TML(\mathbf{v}, Vol(\hat{\mathbf{x}}_{cnd}), Vol(\hat{\mathbf{x}}'_{cnd}))$ denotes a triplet margin loss [36], which uses $\mathbf{v}$ as the “anchor,” $Vol(\hat{\mathbf{x}}_{cnd})$ as the “positive example” that should be close to $\mathbf{v}$, and $Vol(\hat{\mathbf{x}}'_{cnd})$ as the “negative example” that should deviate from $\mathbf{v}$ by a margin compared to $Vol(\hat{\mathbf{x}}_{cnd})$. Here, $\hat{\mathbf{x}}'_{cnd}$ denotes a random synthetic segmentation generated by the prior network and the generator based on $\hat{\mathbf{z}}_{rnd}$ and $\mathbf{y} + \mathbf{y}_n$, where $\mathbf{y}_n$ has the same size of $\mathbf{y}$ and is sampled from a standard Gaussian.

$$\begin{aligned} \mathcal{L}_{c2}(\mathbf{x}, \mathbf{y}, \hat{\mathbf{z}}_{rnd}; \omega) = & \\ & D_\omega(\hat{\mathbf{x}}_{cnd}) + D_\omega(\hat{\mathbf{x}}_{rec}) - 2D_\omega(\mathbf{x}) + \\ & \lambda_5 ((\|\nabla_{\tilde{\mathbf{x}}} D_\omega(\tilde{\mathbf{x}})\|_2 - 1)^2 + (\|\nabla_{\tilde{\mathbf{x}}'} D_\omega(\tilde{\mathbf{x}}')\|_2 - 1)^2), \end{aligned} \quad (14)$$

where ω denotes that this function updates the discriminator. Minimizing $D_\omega(\hat{\mathbf{x}}_{cnd}) + D_\omega(\hat{\mathbf{x}}_{rec}) - 2D_\omega(\mathbf{x})$ drives the discriminator to give real segmentations higher “scores” and give the reconstructed and synthetic ones lower “scores,” i.e., having a stronger discriminative capability. The term $\lambda_5 ((\|\nabla_{\tilde{\mathbf{x}}} D_\omega(\tilde{\mathbf{x}})\|_2 - 1)^2 + (\|\nabla_{\tilde{\mathbf{x}}'} D_\omega(\tilde{\mathbf{x}}')\|_2 - 1)^2)$ computes the gradient penalty [13] that regularizes the training, where $\tilde{\mathbf{x}} = \epsilon\mathbf{x} + (1 - \epsilon)\hat{\mathbf{x}}_{cnd}$, $\tilde{\mathbf{x}}' = \epsilon'\mathbf{x} + (1 - \epsilon')\hat{\mathbf{x}}_{rec}$, $\epsilon, \epsilon' \sim U[0, 1]$.

$$\begin{aligned} \mathcal{L}_{c3}(\mathbf{x}, \mathbf{y}, \hat{\mathbf{z}}_{rnd}; \eta) = & \\ & C_\eta(\hat{\mathbf{z}}_{cnd}) + C_\eta(\hat{\mathbf{z}}_{rec}) - 2C_\eta(\hat{\mathbf{z}}_{rnd}) + \\ & \lambda_6 ((\|\nabla_{\tilde{\mathbf{z}}} C_\eta(\tilde{\mathbf{z}})\|_2 - 1)^2 + (\|\nabla_{\tilde{\mathbf{z}}'} C_\eta(\tilde{\mathbf{z}}')\|_2 - 1)^2), \end{aligned} \quad (15)$$

where η denotes that this function updates the code discriminator. Minimizing $C_\eta(\hat{\mathbf{z}}_{cnd}) + C_\eta(\hat{\mathbf{z}}_{rec}) - 2C_\eta(\hat{\mathbf{z}}_{rnd})$ drives the code discriminator to have a stronger discriminative capability against the outputs of the prior network and encoder. The last term also denotes a gradient penalty, where $\tilde{\mathbf{z}} = \hat{\epsilon}\hat{\mathbf{z}}_{rnd} + (1 - \hat{\epsilon})\hat{\mathbf{z}}_{cnd}$, $\tilde{\mathbf{z}}' = \hat{\epsilon}'\hat{\mathbf{z}}_{rnd} + (1 - \hat{\epsilon}')\hat{\mathbf{z}}_{rec}$, and $\hat{\epsilon}, \hat{\epsilon}' \sim U[0, 1]$. Furthermore, $\lambda_1, \lambda_2, \lambda_3, \lambda_4, \lambda_5$ and λ_6 are hyperparameters for balancing loss terms.

The prior network is implemented as an FFN block with three linear layers, i.e., $\hat{z}_{cnd} = \hat{z}_{rnd} + FFN_{prior}(\mathbf{y})$. The other modules employ corresponding structures in α -GAN. We adopted the Adam optimization algorithm as well. After training, given an individual with the feature vector $\hat{\mathbf{y}}$, we can utilize the prior network and the generator to conditionally generate an individual-specific segmentation $\hat{\mathbf{x}} = G_{\theta}(P_{\psi}(\hat{\mathbf{z}}|\hat{\mathbf{y}}))$, $\hat{\mathbf{z}} \sim \mathcal{N}(\mathbf{z}; \mathbf{0}, \mathbf{I})$.

Acknowledgments

This work was partially funded by the University Research Priority Program “Dynamics of Healthy Aging” at the University of Zurich and the Swiss National Science Foundation through project MediaGraph (contract no. 202125). Data collection and sharing for this project was provided by the Cambridge Centre for Ageing and Neuroscience (CamCAN). CamCAN funding was provided by the UK Biotechnology and Biological Sciences Research Council (grant number BB/H008217/1), together with support from the UK Medical Research Council and University of Cambridge, UK.

Author Contributions

R.W., L.R., S.M., C.R., M.M., and A.B. contributed to the proposal and conceptualization of the research question and the general framework and idea of this work. R.W. and L.R. contributed to the design, implementation, training, and evaluation of deep generative models. S.M., C.R., M.M., and A.B. contributed to the design of experiments and analysis of experimental results. R.W. contributed to the writing of the whole paper. S.M. contributed to the discussion section. L.R., S.M., C.R., M.M., and A.B. contributed to the proofreading and revision of the whole paper. Additionally, M.M. and A.B. contributed to the data and resource acquisition as well as the planning and coordination of the whole work.
